ABSTRACT

In this research, a Feed-Forward Artificial Neural Network design was implemented on Xilinx Spartan 3S1000 Field Programable Gate Array using XSA-3S Board and prototyped blood type classification device. This research uses blood sample images as a system input. The system was built using VHSIC Hardware Description Language to describe the feed-forward propagation with a backpropagation neural network algorithm. We use three layers for the feed-forward ANN design with two hidden layers. The hidden layer designed has two neurons. In this study, the accuracy of detection obtained for four-type blood image resolutions results from 86%-92%, respectively.

1. Introduction

Blood type is a distinctive feature that every person has. Identification of blood type is important in the case of blood transfusion. There are 4 blood types, i.e., A, B, AB, and O. In the world of medication, medical instances still use conventional ways of identifying blood types. The conventional way is achieved by dripping antiserum reagent to a blood sample. After that, conglomeration will occur, and the tester will have to compare the reagent-dripped sample with another sample with a different antiserum reagent in medical. In big-scale sample testing, this method will not be efficient as it takes a very long time and can cause dissatisfaction to the customers who wish to test their blood samples. Hence, automation of blood type identification is needed [1]-[3].

Using a Field Programmable Gate Array, an electronic and logical device can be designed and used anywhere and anytime with digital circuits. FPGAs have higher speed and smaller size for real-time application than the VLSI design. It also provides flexibility and yields the availability of fast special-purpose hardware for wide applications in programmable systems. For the neural network-based instrument prototype in a real-time application, conventional VLSI neural chip design suffers the limitation in time and cost. In addition, artificial neural network based on FPGAs has fairly achieved with classification application [4].

This research will involve implementing Artificial Neural Network (ANN) by image processing with the pre-processing method. The image can be used as an input with the algorithm designed so the corresponding output will be achieved according to what's been modeled. With the use of ANN in FPGA, prototyping of blood type classification and identification device was assumed to have an excellent accuracy [5], [6] compare to others [7]-[9].

2. System Design

2.1. Pattern Recognition

Pattern recognition is necessary to determine the type of blood type, define entities, and identify their features. These features are used to distinguish a pattern from others. A good feature is a feature that has a high distinguishing power so that the grouping based on the characteristics they have can be done with optimal accuracy.

The essence of pattern recognition recognizes an object by using various modes, which have a high level of accuracy in the process of recognition. A high degree of accuracy is that an object manually (by humans) cannot be recognized but when using one of the introduced methods of recognition. Some differences in a blood sample after mixed with anti-A and anti-B serum are depicted in Figure 1.

The input systems have been taken from offline pictures captured by a digital Sony DSC w170 (10 MP) camera. There were four image types used, as depicted in Table 1. Resolutions for an image captured are 32x32, 48x48, and 64x64.
2.2. Training

The training used a backpropagation algorithm to train each blood group to form a pattern or characteristic for each blood group. This scenario is done in MATLAB software, as described in Figure 2.

This training aims to know the values of the bits ‘1’ number in each sample as a distinguishing feature. It also obtained the value of final weights used in the design-
forward propagation in FPGA with VHSIC Hardware Description Language (VHDL) as described in Figure 3.

In addition to obtained patterns, the training results are also known to the values of final weights used in testing steps.

2.3. Maintaining the Integrity of the Specifications

At this stage, two tests were conducted, i.e., testing with simulation and testing in implementation. Simulation tests are performed to ensure that the created program can run as designed, while implementation testing aims to ensure that the program can be implemented.

2.4. System Block Diagrams

![Figure 4 Hardware System Block Diagram for Blood Identification using FF-ANN](image)

We design the hardware implementation using several steps shown in Figure 4. After several simulations for pre-processing and training, we prepared 40 blood image samples for each type with various resolutions, i.e., 32x32, 48x48, 64x64, 80x80, and 96x96 pixels, using MATLAB.
3. Implementation

3.1. RTL Simulation

This simulation is performed on the blocks that make up the ANN implementation on the FPGA to determine the blood type. The purpose of the simulation is to ensure that the program is designed to run in accordance with the desired system, so hopefully, no errors when done implementation on the FPGA. Figure 5 shows the top-level block implemented.

![Top Level Block](image)

**Figure 5** Top Level Block

3.2. Preprocessing

The pre-processing block is the first block that processes the inputs. Inputs of the 8-bit vector are compared to the gray threshold level used. The resulting threshold value is inverted so that the white pixel value should be '1'. Then the value becomes '0'. A similar thing is also done on the pixel value for black. The pre-processing timing diagram simulation shows in Figure 6.

![Preprocessing simulation results](image)

**Figure 6** Preprocessing simulation results

In the control counter program, there are two programs which consist of counter and memory. The results of the control-counter timing diagram simulation are shown in Figure 7.
Figure 7 Control Counter Simulation Results

The counter program is used to calculate the number of bits ‘1’ from the pre-processing block. The designed counters are used with the incoming images number of inputs to the system.

The memory used is dual input and dual output. The memory's function is to store the calculation results temporarily, and the calculation results will be issued when conditions are met.

3.3. Grouping by Pattern

Figure 8 Simulation Result of Pattern Grouping

The input that goes into the grouping or pattern selection resulting in a counter bit ‘1’ from the input in the control-counter block. The pattern grouping is based on the ratio of the total number of inputs to the input. The total number of inputs is adjusted to the size of the input image used in the test. Then the pattern obtained
will be used to determine the weights corresponding to the pattern. Then the obtained weights used for the forward propagation process to test inputs entered and determine the type of group (A, B, AB, or O) as shown in Figure 8.

3.4. Forward Propagation

Advanced propagation is used in the testing process of the backpropagation algorithm of the final weights obtained in the training process of the input. This process is applied in FPGA in this research.

The output of forwarding propagation is then threshold to simplify the output with 0.5 where the value above 0.5 is ‘1’ and below 0.5 means ‘0’ as shown in Figure 9.

3.5. Hardware Implementation

Xilinx Spartan 3S1000 on XSA-3S Board was used to test our implemented algorithm, as shown in Figure 10. This low-cost board were manufactured by Xess Corp., USA for developing LSI design on FPGA.

![XSA 3S1000 From XESS Corp. Showing A Blood Type Result](image)
This board meets our requirements since it uses a Xilinx XC3S1000 chip, complete with XC9572XL CPLD, 32 MByte SDRAM, 2 MByte Flash, and 100 MHz oscillator. It has 4 DIP switches for input and output, 2 pushbuttons, and 7-segment LED. The feed-forward artificial neural network algorithm was synthesized, implemented, and placed based on this FPGA using Xilinx ISE and GXSLOAD software. Targeting this board, we got the system synthesis report as shown in Table 1.

| Logic Utilization | Used | Available | Utilization |
|-------------------|------|-----------|-------------|
| Number of Slices  | 746  | 7680      | 9%          |
| Number of Slice Flip Flops | 254  | 15360     | 1%          |
| Number of 4 input LUTs     | 1326 | 15360     | 8%          |
| Number of Bonded IOBs     | 24   | 173       | 13%         |
| Number of MULT 18x18s    | 8    | 24        | 33%         |
| Number of GCLKs         | 2    | 8         | 25%         |

4. Performance Test Results

The test implementation for 40 blood images where each resolution is in accordance with 40 pairs of blood sample images was performed. Based on the test result, based on two parameters, a comparison of resolution with a mean and median number of bit ‘1’ is shown in Figure 11.

As we can see from Figure 11, there are differences in the accuracy of reading the image training in Matlab and FPGA for 32x32, 48x48, 64x64, 80x80, and 96x96 resolutions. Matlab shows that the graphics are constant with an accuracy rate of 92%. Several images are read incorrectly for each resolution. This is because the image's shape has been dripped with the antisera and is not coagulated perfectly. Then, blood droplets and antisera of each image are not measured to each other.

Whereas in the FPGA, the accuracy has decreased at 80x80 and 96x96 resolutions. This is because the value of comparing the resolution in the FPGA is rounded. This rounding is done because the effect of comma-behind values in the FPGA cannot be read, so rounding is needed.
5. Conclusions

ANN implementation research on FPGA can only be done on the forward propagation of the backpropagation algorithm. This is because of the limitations of the software used to build programs and memory FPGA. Implementation of ANN forward propagation of backpropagation algorithm on FPGA Spartan XSA 3S1000 to determine blood type can be applied with 9% slice requirement, 1% flip flop slice, 4 input LUTs 8%, bounded IOB 13%, MULT18X18s 33%, and GCLKs 25%. The ANN forward propagation test of the backpropagation algorithm on the FPGA to determine the blood type obtained a variety of accuracy performance. Based on the grouping of patterns with the comparison of MATLAB simulation, we obtained an accuracy of FPGA are 92%, 92%, 92%, 90% dan 86% for 32x32, 48x48, 64x64, 80x80, and 96x96 pixel blood image resolutions, respectively. The result of accuracy with a ratio of median value almost equal to the comparison of mean value, accuracy will increase with a magnification of resolution. In the forward propagation algorithm implementation, the test results are highly dependent on the characteristic of the pattern set. If the image resolution used is changed, then the pattern will also change, which affects the output obtained. The value of test accuracy is influenced by the internal factors of the system (pattern determination) and external factors (the absence of rules in the administration of antisera liquid).

6. Future Work

From the results of this research, we plan to develop the products in a real-time system using a low-cost HD camera and internet-based system. We need to develop the system for applied implementation to fulfill the market requirements.
