Abstract

Introduction: There is conflicting data as to whether obesity is an independent risk factor for mortality in severe pandemic (H1N1) 2009 influenza (A(H1N1)pdm09). It is postulated that excess inflammation and cytokine production in obese patients following severe influenza infection leads to viral pneumonitis and/or acute respiratory distress syndrome.

Methods: Demographic, laboratory and clinical data prospectively collected from obese and non-obese patients admitted to nine adult Australian intensive care units (ICU) during the first A(H1N1)pdm09 wave, supplemented with retrospectively collected data, were compared.

Results: Of 173 patients, 100 (57.8%), 73 (42.2%) and 23 (13.3%) had body mass index (BMI) <30 kg/m², ≥30 kg/m² (obese) and ≥40 kg/m² (morbidly obese) respectively. Compared to non-obese patients, obese patients were younger (mean age 33.4 vs. 48.4 years, p = 0.035) and more likely to develop pneumonitis (61% vs. 44%, p = 0.029). Extracorporeal membrane oxygenation use was greater in morbidly obese compared to non-obese patients (17.4% vs. 4.7%, p = 0.04). Higher mortality rates were observed in non-obese compared to obese patients, but not after adjusting for severity of disease. C-reactive protein (CRP) levels and hospital length of stay (LOS) were similar. Amongst ICU survivors, obese patients had longer ICU LOS (median 11.9 vs. 6.8 days, p = 0.017). Similar trends were observed when only patients infected with A(H1N1)pdm09 were examined.

Conclusions: Among patients admitted to ICU during the first wave of A(H1N1)pdm09, obese and morbidly obese patients with severe infection were more likely to develop pneumonitis compared to non-obese patients, but mortality rates were not increased. CRP is not an accurate marker of pneumonitis.

Introduction

Critical care data from the first pandemic influenza wave of 2009 (hereafter A(H1N1)pdm09) in Australia and New Zealand revealed that 28.6% of patients admitted to intensive care units (ICUs) were obese (defined as a body-mass index [BMI; calculated as weight in kilograms divided by height in metres squared] >35 kg/m²) [1], an observation not noted previously in severe influenza infection [2,3]. Post hoc analysis revealed that the rate of obesity (BMI ≥30 kg/m²) in ICU patients (44%) was much higher than in the general Australian and New Zealand adult population (23.7%–27.1%) [4,5].

This is comparable to data from the United States of America (USA), where 51% of patients hospitalized during the first pandemic phase in California had BMI ≥30 kg/m², 2.2 and 1.5 times the prevalence of obesity in California and the USA respectively [6]. Of A(H1N1)pdm09-related deaths (overall mortality rate was 17%), 61% had BMI ≥30 kg/m² and 30% had BMI ≥40 kg/m².

Animal models have shown that obesity is associated with altered immune and inflammatory responses upon infectious stimuli [7]. Compared to lean mice, influenza infection in obese mice deregulates immune responses, and results in mortality rates...
also have high levels of circulating C-reactive protein (CRP) pro-inflammatory state [11]. Overweight and obese individuals inflammatory cytokines are also produced, the net effect is a (MCP-1) and interleukin-8 (IL-8) [9,10,11]. Although anti-

relationship between BMI (as a marker of obesity), CRP and viral infection [6,17,18,19,20].

infection may lead to viral pneumonitis and/or acute respiratory distress syndrome (ARDS) [14], which are postulated to be responsible for respiratory failure in obese patients with severe A(H1N1)pdm09 infection [15]. Although there may be multiple factors to account for poor outcomes in critically ill obese patients (including multiple co-morbidities, difficult and prolonged mechanical ventilation, increased nosocomial infections and other complications [16]), it has been suggested that obesity is an independent risk factor for death in severe A(H1N1)pdm09 infection [6,17,18,19,20].

This study aims to describe the demographic characteristics and outcomes of obese patients with severe influenza infection during the first A(H1N1)pdm09 wave in Australia; and to determine the relationship between BMI (as a marker of obesity), CRP and viral pneumonitis in severe influenza infection.

Methods

The Australian and New Zealand Intensive Care Society (ANZIC) Influenza Investigators prospectively collected demographic, clinical and laboratory data from 722 patients admitted to 187 Australian and New Zealand adult and pediatric ICUs during the first A/H1N1/pdm09 pandemic wave from June 1st to August 31st, 2009 [1]. The ANZICS Centre for Outcome and Resource Evaluation (ANZICS-CORE) collects data including postcodes, severity scores and associated biochemical and physiological values from the first 24 hours of ICU admission on patients admitted to 85% of ICUs in Australia and New Zealand. All patients defined as having ARDS or viral pneumonitis by the treating physician were grouped together as “pneumonitis”.

ANZIC and ANZICS-CORE data from adult patients admitted to nine ICUs in two Australian states, New South Wales and Western Australia were linked, and supplemented with CRP data (measured on admission to hospital and ICU) retrospectively collected from each hospital’s laboratory information system. The SEIFA (socioeconomic indexes for areas) index of disadvantages (available from http://www.abs.gov.au/AUSSTATS/abs@.nsf/DetailsPage/2033.0.55.0012006?OpenDocument), which summarizes various attributes (including income, unemployment, education attainment) and median household income (available from http://www.censusdata.abs.gov.au/censusOutput/abs@.cpp2006.nsl) for each patient’s residential postal area was identified using the most recent census data (collected in 2006) from the Australian Bureau of Statistics. SEIFA is comprised of a score and rank, with lower scores and rank indicative of lower socioeconomic status (SES). The SEIFA score is standardized against a mean of 1000 with a standard deviation of 100, and SEIFA ranking ranged from 12 to 2450 within this cohort.

Data were analyzed using SAS software, version 9.2 (SAS Institute Inc., Cary, NC, USA). Descriptive statistics for all study variables were obtained. Univariate analyses were performed using chi-square test for equal proportion (or Fisher’s exact test where numbers were small), student’s t-test or Wilcoxon rank-sum test as appropriate, with results presented as numbers (%), mean (standard deviation) or median (interquartile range) respectively. Whilst event numbers were too small to facilitate the valid development of prediction models for outcome, to establish whether observed univariate effects were independent of patient severity, multivariable logistic and log-linear regression models were used to determine the relationships between obesity and outcome after adjustment for the APACHE III health status score, with results as odds ratios (95%CI) and geometric means (95%CI) respectively. A two sided p-value of <0.05 was considered to be statistically significant.

Ethics Statement

Data are collected under the Quality Assurance Legislation of the Commonwealth of Australia (Part VC, Health Insurance Act 1973, Commonwealth of Australia). Such data are collected with government support and funding and are submitted on behalf of each ICU director. Each hospital allows subsequent use of this data as appropriate under the ANZICS-CORE standing procedures and in compliance with the ANZICS-CORE terms of reference.

Results

Data was available from 173 adults admitted to ICU with laboratory-confirmed influenza during the first pandemic wave of 2009. The median age was 46 years, 55% were female, and 12.7% (or 23.2% of all females) were pregnant. Mechanical ventilation and extracorporeal membrane oxygenation (ECMO) was used in 63.6% and 6.4% of patients respectively. Median length of ICU and hospital stay was 8.4 (IQR 2.8–16.4) and 15.6 (IQR 8.0–30.5) days respectively. The overall mortality rate was 12.7%. The majority of patients were infected with either A/H1N1/pdm09 (83.8%) or seasonal influenza A/H3N2 (9.8%). A diagnosis of pneumonitis was recorded in 49.7% of patients and concurrent bacterial pneumonia was diagnosed in 13.9% of patients. Baseline patient characteristics for all patients, and those infected with A/H1N1/pdm09 (n = 145) are shown in Table 1.

Tables 2 and 3 show the characteristics, laboratory parameters and outcomes of non-obese, obese and morbidly obese patients admitted to ICU with severe influenza during the first pandemic wave and those with A/H1N1/pdm09 infection respectively.

Of 173 patients, 100 (57.8%), 73 (42.2%) and 23 (13.3%) had BMI $30 kg/m², ≥30 kg/m² and ≥40 kg/m² respectively. On univariate analyses, obese patients (BMI ≥30 kg/m²) were younger (mean age 43.4 vs. 48.4 years, p = 0.035) and more likely to be diagnosed with pneumonitis (61% vs. 44%, p = 0.029) when compared to non-obese patients. Morbidly obese patients (BMI ≥40 kg/m²) were more likely to require ECMO (17.4% vs. 4.7%, p = 0.04). These trends were also observed when patients with A/H1N1/pdm09 only were analyzed.

While obesity was significantly more prevalent amongst patients with pneumonitis (50% vs. 33%, p = 0.029), this result was no longer significant after adjustment for patient severity (OR 1.75 [0.91–3.37], p = 0.10). However, obesity (OR 2.19 [1.12–4.71], p = 0.045), but not morbid obesity (OR 2.11 [0.69–6.45], p = 0.18), was an independent predictor of pneumonitis after adjusting for age and chronic lung disease.
Table 1. Baseline characteristics of patients admitted to intensive care unit during the first pandemic (H1N1) 2009 influenza wave of 2009.

| Characteristic                          | All patients (n = 173) | Patients with A(H1N1)pdm09 only (n = 145) |
|----------------------------------------|------------------------|-------------------------------------------|
| **Age – years**                         |                        |                                           |
| Median                                 | 46                     | 47                                        |
| IQR                                    | 34–84                  | 34–55                                     |
| **Female sex – no. (%)**                | 95 (55%)               | 73 (50.3%)                                |
| **Pregnant – no. (%)**                  | 22 (12.7%)             | 20 (13.8%)                                |
| **Ethnicity – no. (%)**                 |                        |                                           |
| Caucasian                              | 130 (75.1%)            | 106 (73.1%)                               |

| Concurrent bacterial pneumonia         | 24 (13.9%)             | 17 (11.7%)                                |
| Exacerbation of airflow limitation     | 29 (16.7%)             | 23 (15.9%)                                |
| **Length of stay – days**              |                        |                                           |
| ICU                                    | 8.38                   | 8.6                                       |
| IQR                                    | 2.8–16.4               | 2.8–17.9                                  |
| Hospital                               | 15.6                   | 16.2                                      |
ICU and hospital mortality rates were significantly higher for non-obese patients (17% vs. 5%, p = 0.02 and 20% vs. 6%, p = 0.016 respectively), but median APACHE II and APACHE III scores on admission were also significantly higher (17 vs. 15, p = 0.029 and 56 vs. 48.5, p = 0.012). Consequently, after adjustment for patient severity, obesity was no longer a significant predictor of either ICU or hospital mortality (OR 0.42 [0.10–1.77], p = 0.24 and OR 0.37 [0.11–1.30], p = 0.12 respectively).

Similarly, mortality rates between morbidly obese and non-morbidly obese patients were significant at a univariate level, but became non-significant after adjustment for patient severity. There was a trend towards longer ICU and hospital length of stay (LOS) in obese and morbidly obese patients. However, for ICU survivors, obese patients did have longer median ICU LOS (11.9 vs. 6.8 days, p = 0.017), with this result remaining significant after adjustment for patient severity (geometric mean [95%CI] 9.4 [7.1–12.4] vs. 6.1 [4.8–7.9], p = 0.03).

CRP levels were not significantly higher when obese and non-obese patients were compared on admission to hospital and ICU. Obese and morbidly obese patients tended to have lower median household incomes, SEIFA scores, and SEIFA rankings.

Discussion

Although obese patients are more likely to be hospitalized with A(H1N1)pdm09 infection [18,21], there are conflicting data on whether obesity is an independent risk factor for increased mortality in severe A(H1N1)pdm09 infection. Diaz et al, Kumar et al and Estenssoro et al all noted that obese patients were more likely to require mechanical and prolonged ventilation, but not more likely to die [22,23,24]. Rodriguez et al in fact noted improved mortality rates of obese patients with severe A(H1N1)pdm09 infection, paralleling the experience of obese patients suffering other critical illness [25,26,27]. This is in contrast to data suggesting that obesity is an independent risk factor for increased mortality [6,17,18,19,20]. A potential explanation for this discrepancy is that only subsets of obese patients are at increased risk for severe infection; obese patients that develop pneumonitis.

Similar to previous reports [28], obese and morbidly obese patients in our cohort were more likely to develop pneumonitis compared to non-obese patients. Although Rodriguez et al noted that obese patients had improved mortality rates on univariate analyses, logistic regression analysis showed that higher APACHE II scores were independently associated with increased mortality [25]. Our findings are concordant with those of Rodriguez et al; non-obese patients had higher mortality rates on univariate analysis, but this observation was not maintained after adjustment for severity of illness as reflected by APACHE II and APACHE III scores. On the other hand, obese patients may have had less severe disease as reflected by higher albumin levels and lower white cell counts, CRP, urea, APACHE II and APACHE III scores.

Previous meta-analyses prior to the 2009 pandemic have identified that obese patients have similar or greater levels of morbidity, but not mortality, following admission to ICU and that obesity may in fact be protective [26,29]. Our data suggests that both obese and non-obese patients have similar levels of mortality; however, non-obese patients tended to be older. Although younger patients with A(H1N1)pdm09 are more likely to be hospitalized, ICU admission and mortality rates were higher in the elderly. If this is the case, obesity may in fact be protective for younger patients. However, morbidly obese patients were more likely to be older, with a median age of 56 vs. 48.5, p = 0.012. Consequently, after adjustment for age, obesity was no longer a significant predictor of mortality.

In the present study, obesity was an independent predictor of pneumonitis after adjusting for age and chronic lung disease. Furthermore, clinicians may have intervened with more advanced levels of respiratory support in the obese patients pre-emptively and more readily prior to even more significant respiratory failure. Although our obese patients were more likely to develop pneumonitis, they were also more likely to recover once the acute lung insult resolved. The duration of mechanical ventilation was similar between obese and non-obese patients, comparable to the experience of critically ill patients with respiratory failure prior to the 2009 pandemic [26].

Obese and morbidly obese patients had greater levels of hypoxemia, as reflected by the lower partial pressures of arterial oxygen and higher fractions of inspired oxygen. Presumably, obesity per se results in greater levels of hypoxemia for any given pulmonary insult, as obese patients have reduced lung, chest wall compliance, and higher airway resistance, resulting in greater ventilation/perfusion mismatching [26]. There was an increased use of ECMO in both these groups of patients, reflecting perceived inadequate ventilation of these patients by conventional mechanical ventilation. There is conflicting evidence on the efficacy of ECMO in this setting; Noah et al observed improved mortality rates [31], whilst Davies et al noted worse outcomes in patients receiving ECMO for severe A(H1N1)pdm09 infection compared to those receiving mechanical ventilation alone [32]. However, in the latter group, those receiving ECMO had severe respiratory failure treated with at least one other method of rescue ARDS therapy (rebreath manoeuvres, prone-positioning, high-frequency oscillatory ventilation and/or inhaled nitric oxide or prostacyclin) prior to ECMO, and the majority were referred from other hospitals [32].

Previous investigators have observed significantly higher levels of pro- and anti-inflammatory cytokines (including IL-6, IL-8, MCP-1) in patients with severe A(H1N1)pdm09 infection [33,34,35]. In contrast to data from Hagau et al [35], our data suggests that CRP alone may not be an accurate marker for excess cytokine production in severe A(H1N1)pdm09 infection, as levels were similar in both obese and morbidly obese, compared to non-obese, patients on admission to hospital and ICU, despite the increased frequency of pneumonitis in the obese group. A
| Parameter | Non-obese (n = 100) | Obese* (n = 73) | P-value | Non-morbidly obese (n = 150) | Morbidly obese* (n = 23) | P-value |

A plausible explanation for similar CRP levels in both groups of patients is the possibility of concurrent bacterial co-infection, as other investigators have noted higher CRP values in this setting [19,36]. Although evidence of bacterial pneumonia was present in only 13.9% of patients, this may have been underestimated as radiological evidence and microbiological confirmation of bacterial pneumonia was not always available. Other investigators have noted higher CRP values in this setting although evidence of bacterial pneumonia was present in other investigators have noted higher CRP values in this setting although evidence of bacterial pneumonia was present in only 13.9% of patients, this may have been underestimated as radiological evidence and microbiological confirmation of bacterial pneumonia was not always available. Other investigators have suggested co-infection rates of ~25% [23,37].

The prevalence of obesity is inversely proportional to the SES in children and adults [38,39]. In addition, people from lower socioeconomic backgrounds have increased rates of influenza, and are less likely to be vaccinated against influenza [40,41]. Although not statistically significant, trends of lower SEIFA scores, SEIFA rankings and median household incomes, based on residential postcode areas, were observed in our obese patients. However, postcode areas may contain a mix of people from low, medium or high socioeconomic backgrounds, potentially confounding the use of postcodes alone as a measure of SES.

Unlike some countries in the Northern Hemisphere, Australia did not have a “pre-first” pandemic wave, thus providing us with a unique opportunity to study the effects of a newly circulating pandemic influenza virus on susceptible obese populations with little pre-existing immunity. The data presented herein was collected from nine different ICUs with ECMO facilities during the first pandemic wave in the Southern Hemisphere, which coincided with the winter of 2009, and prior to the introduction of the monovalent A(H1N1)pdm09 vaccine in Australia [42].

BMI and CRP data were not available for the entire cohort of patients admitted to Australian ICUs during the first pandemic wave [1]. Nevertheless, the 173 patients in our study are representative of the original cohort, with similar rates of obesity, demographics, and outcomes. Although CRP data were obtained retrospectively, this parameter was measured at the time of hospital and ICU admission. Influenza A subtypes were also not available in all patients, as retrospective diagnoses were made serologically in some instances [43]. However, these were likely to be A(H1N1)pdm09, given the epidemiology of circulating viruses at the time. We were also not able to retrospectively measure levels of pro- and anti-inflammatory cytokines or influenza viral loads (and hence viral clearance), which we postulate would have been higher in obese patients. The use of anti-inflammatory and/or immunomodulatory agents such as corticosteroids and statins [44,45,46,47] that may mitigate the excessive inflammatory response were also not recorded.

In conclusion, obese patients with severe A(H1N1)pdm09 infection from the first pandemic wave in Australia were more likely to develop pneumonitis compared to non-obese patients, but mortality rates were similar between the two groups after adjusting for severity of disease. Although there is on-going debate as to whether obesity is a risk factor for severe A(H1N1)pdm09 infection, annual influenza vaccination should be prioritized in this group given the increased risk of serious complications from seasonal influenza infection [6,8,21]. Current Australian and United Kingdom vaccination guidelines do not specifically recommend annual influenza vaccination in the obese [48,49].

### Table 2. Cont.

| Parameter                                      | Non-obese (n = 100) | Obese* (n = 73) | P-value | Non-morbidly obese (n = 150) | Morbidly obese* (n = 23) | P-value |
|------------------------------------------------|---------------------|-----------------|---------|-----------------------------|--------------------------|---------|

### Table 3. Cont.

| Parameter | Non–obese (n = 83) | Obese* (n = 62) | P–value | Non–morbidly obese (n = 125) | Morbidly obese* (n = 20) | P–value |
|-----------|------------------|----------------|---------|-----------------------------|-------------------------|---------|
| Duration of mechanical ventilation (days) (Median, IQR) | 5 (0–11) | 8 (1–7) | 0.06 | 5 (0–12) | 9.5 (3–14) | 0.18 |
| ECMO – no. (%) | 4 (5%) | 7 (11%) | 0.20 | 7 (6%) | 4 (20%) | 0.046 |
| Vasopressor – no. (%) | 33 (40%) | 19 (31%) | 0.3 | 45 (36%) | 7 (4%) | 1.00 |
| Renal replacement therapy – no. (%) | 8 (10%) | 5 (8%) | 1.00 | 12 (10%) | 1 (5%) | 1.00 |
| Length of stay (days) (Median, IQR) | ICU | 7.24 (2.5–13.1) | 11.2 (3.1–23.1) | 0.08 | 7.9 (2.5–16.6) | 11.5 (6.8–23.7) | 0.06 |
| Excluding those that died | 7.1 (3.4–12.7) | 12.5 (3.9–24) | 0.02 | 9 (3.4–17.2) | 12.5 (10.3–19.8) | 0.07 |
| Hospital | 15.4 (7.3–27.2) | 19.4 (8–34.2) | 0.25 | 15.6 (6.7–30.4) | 18.4 (11.6–35.2) | 0.28 |
| Death – no. (%) | 16 (19%) | 5 (8%) | 0.09 | 19 (15%) | 2 (10%) | 0.74 |
| In ICU | 18 (22%) | 4 (6%) | 0.018 | 20 (16%) | 2 (10%) | 0.74 |
| Median household income/week (AUD) (Mean, SD) | 1065.8 (262.5) | 1004.8 (215.2) | 0.14 | 1040.8 (249.4) | 1033.2 (216.6) | 0.9 |
| SEIFA score (Mean, SD) | 975.9 (82.3) | 974.6 (73.4) | 0.92 | 976.4 (80.2) | 968.7 (67.1) | 0.68 |
| SEIFA rank (Mean, SD) | 1094 (720.3) | 1066.4 (676.7) | 0.82 | 1101.2 (695.7) | 963.2 (731.3) | 0.41 |

### Definitions of abbreviations: APACHE = Acute Physiology, Age, and Chronic Health Evaluation; ARDS = Acute respiratory distress syndrome; AUD = Australian dollar; BMI = Body mass index (calculated as weight in kilograms divided by height in metres squared); ECMO = Extracorporeal membrane oxygenation; ICU = Intensive care unit; IQR = Interquartile range; SD = Standard deviation; SEIFA = Socioeconomic indexes for areas.

*Obese BMI ≥30 kg/m².

*Morbidly obese BMI ≥40 kg/m².

The nine hospitals contributing data are Westmead Hospital, Blacktown Hospital, Nepean Hospital, Liverpool Hospital, Campbelltown Hospital, Royal Prince Alfred Hospital (New South Wales); Royal Perth Hospital, Sir Charles Gardiner Hospital and Fremantle Hospital (Western Australia).

Author Contributions

Data collection and collation: JK CCB HF MJB DVP. Conceived and designed the experiments: JK DED JRI. Analyzed the data: JK MJB. Wrote the paper: JK MJB CCB HF IMS SAW DED JRI.
