Abstract
Eosinophilic sialodochitis (ES) is a rare clinical entity which presents as recurrent major salivary gland swelling and the presence of eosinophil-rich mucus plugs or histopathological evidence of eosinophilic infiltration around the larger salivary gland ducts. We present a case of ES not related with underwent a left submaxillectomy because recurrent episodes of submandibular gland swelling associated for the last three years. The laboratory workup demonstrated eosinophils slightly elevated and high levels of immunoglobulin E (IgE) in peripheral blood. Pathology slides confirmed the final diagnosis of ES, showing a dense periductal eosinophil-rich inflammatory infiltrate and periductal fibrosis. Although the entity is well described in the literature, diagnosis is often difficult due to its clinical presentation being similar to other conditions. Lesions that should be taken into consideration in differential diagnosis are mentioned. This will be the first ES case report in Eastern European literature.

Keywords: eosinophilic sialodochitis, salivary gland, eosinophils.

Introduction
Eosinophilic sialodochitis (ES) is one of the rarest known conditions that affect the salivary glands. The disease is characterized by recurrent salivary gland swelling associated with mucous plugs or histological evidence of eosinophilic infiltration around the main salivary gland ducts

Diagnosis of ES is difficult and may be easily confused with either acute inflammatory disorders or chronic conditions that may subsequently cause salivary gland swelling.

Criteria for the identification of ES are regularly based on a list created by Baer et al. [4]: recurrent episodes of parotid and/or submandibular glandular swelling; intra-ductal mucous plugs containing frequent eosinophils; eosinophilia and high levels of immunoglobulin E (IgE) in peripheral blood; associated allergic disease; dilated main salivary ducts; lack of diagnostic criteria for sclerosing disease associated with immunoglobulin G4 (IgG4).

As limitations exist across those criteria, recently Carey et al. [5] propose one algorithm with refined criteria for defining and differentiating ES: (i) intermittent swelling of at least one major salivary gland; (ii) presence of eosinophils in ductal contents; (iii) presence of at least one of the following additional symptoms: itching of the skin overlying the affected gland/pain in the affected gland/ expression of string-like mucous plugs; (iv) exclusion of other causes of salivary gland swelling with eosinophils.

Aim
Here, we present a rare case of ES, discussing the patient’s history, symptoms, diagnosis, and treatment.

Case presentation
A 49-year-old woman sought treatment at the Prof. Dr. Dan Theodorescu Clinical Hospital of Oral and Maxillofacial Surgery, Bucharest, Romania, in May 2019, because recurring episodes of swelling unrelated to mastication and pain of the left submandibular area during the past three years that does not relieve on common nonsteroidal anti-inflammatory drugs. Episodes occurred 2–3 times per year and are not related with food consumption. Also, the patient stated that during this time she also had two episodes of swelling of the left parotid gland, lasting several hours, which remitted spontaneous. Antispasmodic drugs and massage to compress the salivary gland provide variable symptomatic relief, until the moment when the painful episodes became more severe in frequency and duration.

Physical examination at admission revealed a painless diffuse swelling of the left submandibular area gland that is tender upon palpation. On bimanual palpation left submandibular gland was enlarged and firm miming a chronic sclerosing sialadenitis. Introral examination was unremarkable except for palpation of the submandibular duct, which expressed thick mucoid secretions without purulence. Sialoliths were absent. She does not have any palpable cervical nodes. She was not taking any medications and had no history of systemic disorders. Also, she had no past medical history of allergies. The patient quitted smoking five years ago and had no history of alcohol consumption.

The ultrasonography of the submandibular area revealed a heterogeneous echotexture and hypoechoic echogenicity throughout the submandibular gland (Figure 1). Also, we noted dilation of the submandibular ductal system without evidence of sialoliths.

Routine hematological investigations were within normal limit, except eosinophil count of 3.1 mL/µL (normal range 0.04–0.45 mL/µL). The assays for antinuclear antibodies (ANAs), anti-double-stranded deoxyribonucleic acid (DNA) antibodies, and anti-extractable nuclear antigen antibodies including anti-Sjögren syndrome-related antigen A and anti-Sjögren syndrome-related antigen B were all negative; C-reactive protein (CRP), IgG, immunoglobulin A (IgA), immunoglobulin M (IgM), IgG4, ANA and rheumatoid factor levels were normal, but a higher level of IgE was noted: 260 IU/mL (normal range <100 IU/mL). We performed allergy tests, including skin prick tests with a standard panel of allergen extracts, patch tests for allergens and haptens, all of which produced negative results.

The left submandibular gland removal was performed. The patient evolved with no postoperative complications.

Tissue specimens were fixed in 10% neutral buffered formalin for 48 hours followed by paraffin embedding. Five-µm-thick serial sections were obtained from each paraffin block. One section was stained with routine Hematoxylin–Eosin (HE) method for histopathological assessment, the other corresponding sections from each case were selected for immunohistochemistry (IHC). IHC was performed to highlight mast cells (MCs) using monoclonal mouse anti-human mast cell tryptase (MCT) antibody, clone 10D11 (Novocastra, Newcastle, UK). Antigen retrieval was achieved by treating sections with a boiling citric acid buffer solution (0.01 mol/L, pH 6.0) for 10 minutes in a microwave oven. Color was developed in freshly made 3,3'-Diaminobenzidine (DAB). Sections were washed briefly in running tap water and stained lightly with Mayer’s Hematoxylin. Negative controls were obtained by omission of the relevant primary antibody. Immunohistochemical procedures were performed in an automatic manner by using Bond-Max Autostainer (Leica Microsystems, Newcastle, UK), which worked with Bond Polymer Refine Detection system.

Gross examination (Figure 2) revealed the left submandibular gland of 4.5/3.3/1.8 cm, yellow grayish in color, with firm consistency; the lobular contour was preserved; we noted multiple dilations of the intraglandular ducts and marked dilatation of the main submandibular duct, without stones. Histological examination revealed dense eosinophil infiltration around the duct, intraductal mucus plug with eosinophils and fibrin clots and follicular hyperplasia around the ducts (Figures 3–6). Evidence of positive MC infiltration around the large ducts was also found and subsequently confirmed with MCT immunostaining.
The term “eosinophilic sialodochitis” is considered controversial because the term of sialodochitis is commonly used to describe salivary duct dilatation, associated with sialolithiasis [1]. However, sialodochitis is impossible to separate from sialadenitis clinically and the disease appears initially duct associated. The literature reported that the secretion of a fibrinous material containing numerous eosinophils from the glandular duct orifices was a distinctive finding of ES [1–9]. Few histopathological investigations into ES have been published. However, some studies have reported the presence of eosinophils, and fibrin clots containing detached epithelium in the salivary ducts, while others have described hypertrophy of the salivary duct epithelium, as well as lymphocyte infiltration of the surrounding interstitium [2, 3].

In another case report of a patient treated with total parotidectomy, it was noted that fibrin clots continued to be discharged from the opening of the Stensen’s duct. This suggests that sialodochitis fibrinosa is an inflammation of the salivary ducts, rather than of the salivary glands [6].

The etiology of ES is not well understood, although the most accepted hypothesis is that it is an allergic process [7–13]. Support for an allergic etiology is based on significant medical history of asthma and chronic rhinoconjunctivitis in some patients and a raised peripheral eosinophil count in affected patients [9]. In our case, we were unable to correlate symptoms with the consumption of food allergens. However, we found numerous eosinophils in the larger glandular ducts, that could be the result of an allergic reaction at the location.

The diagnosis of ES is difficult as many of the symptoms and findings are nonspecific. Thus, it is necessary to rule out the more common causes of salivary gland swelling, such as sialolithiasis, infectious sialadenitis, Sjögren’s syndrome or sarcoidosis. Visualizing mucous plugs at the Wharton duct papillae is more common for ES; imaging reveals the absence of calculi and laboratory tests can rule out autoimmune etiologies [2]. Our patient’s chief complaint was the recurrent swelling of the left submandibular region over a three-year period. The pressure around the submandibular gland caused the extrusion of the fibrinous material followed by a gush of saliva. We suspected that the material might accompany the secondary bacterial infection of sialolithiasis and performed ultrasonography examination to detect sialoliths. No sialoliths were observed but diffuse swelling of left submandibular gland and dilation of submandibular glandular duct were detected on the ultrasonic images. These findings were consistent with diagnosis of chronic sialodochitis.

Additionally, other diseases that may need to be considered in the differential diagnoses for ES are conditions associated with eosinophils in the salivary gland: Kimura disease, angiolymphoid hyperplasia with eosinophilia and eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg–Strauss syndrome) [4, 5]. IgG4-related sialadenitis is characterized by a dense lymphoplasmacytic infiltrate and severe interstitial fibrosis with loss of acini [4]. There was no abnormal level of serum IgG4 elevation in our patients. Kimura’s disease presents as subcutaneous painless soft tissue swelling in the head and neck, peripheral blood eosinophils increase, lymphoid follicular hyperplasia and germinal center enlargement, eosinophilic infiltration, and accumulation of eosinophilic micro-abscess [4]. Angiolymphoid hyperplasia with eosinophilia is closely related to Kimura’s disease, but histopathology revealed a diffuse inflammatory infiltrate, presence of abundant vascular proliferation with cytoplasmic vacuoles in endothelial cells and eosinophil infiltration [4, 5]. The salivary glands may rarely be involved in EGPA, a condition characterized by asthma, high levels of eosinophils; major histological findings in this condition are the extravascular granulomas, vasculitis, and the eosinophilic infiltrates [4].

Being a rare condition, no treatment has proven effective [13–19]. Gland resection should be considered in case of recurrence [6, 20]. With regards to treatment for our patient, she achieved complete remission of her symptoms after excision of the gland. Additionally, the salivary duct was removed at the same time as the gland itself.

Conclusions

ES is a relatively rare lesion that should be considered in the differential diagnosis of recurrent major salivary gland swelling associated with comorbid atopic disease. According to clinical, ultrasonographic and histological findings associated with increased peripheral eosinophils and total IgE level, the patient was diagnosed with ES.
Histopathological features included diffuse periductal fibrosis with a lymphoplasmacytic infiltrate rich in eosinophils. These findings were very important for distinguishing ES from Kimura’s disease, angiolymphoid hyperplasia with eosinophils and EGPA. The features of these conditions and a differential diagnosis are discussed.

**Conflict of interests**

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interests.

**Authors’ contributions**

O.M.D. and A.B. conceived the original idea and performed data collection. G.C.V. and L.C.P. wrote the main paper. A.C.D. and M.B.B. wrote the Supplementary Information. All authors approved the final version of the manuscript for submission.

**Ethics statement**

We obtained the approval of the Ethics Committee of Prof. Dr. Dan Theodorescu Clinical Hospital of Oral and Maxillofacial Surgery, Bucharest, for the publication of this manuscript (No. 6289/30.07.2021).

**Consent**

Written informed consent was obtained from patient for the publication of any potentially identifiable images or data included in this article.
