ABSTRACT
We report on analysis of the poorly studied source 2RXP J130159.6-635806 at different epochs with ASCA, BeppoSAX, XMM-Newton and INTEGRAL. The source shows coherent X-ray pulsations at a period ~ 700 s with an average spin up rate of about \( \dot{\nu} \sim 2 \times 10^{-13} \text{ Hz s}^{-1} \). A broad band (1-60 keV) spectral analysis of 2RXP J130159.6-635806 based on almost simultaneous XMM-Newton and INTEGRAL data demonstrates that the source has a spectrum typical of an accretion powered X-ray pulsar, i.e. an absorbed power law with a high energy cut-off with a photon index \( \Gamma \sim 0.5-1.0 \) and a cut-off energy of ~ 25 keV. The long term behaviour of the source, its spectral and timing properties, tend to indicate a high mass X-ray binary with Be companion. We also report on the identification of the likely infrared counterpart to 2RXP J130159.6-635806. The interstellar reddening does not allow us to strongly constrain the spectral type of the counterpart. The latter is, however, consistent with a Be star, the kind of which is often observed in accretion powered X-ray pulsars.

Key words: pulsars: individual: 2RXP J130159.6-635806 – gamma rays: observations – X-rays: binaries – X-rays: individual: 2RXP J130159.6-635806

1 INTRODUCTION

On February 7, 2004, during a routine Galactic plane scan, the INTEGRAL observatory detected a source which was not in the INTEGRAL reference catalog. Search in the archive led to the identification of several ROSAT sources in the INTEGRAL error box. Among them 2RXP J130159.6-635806 is the closest one to the best estimate of the source position obtained with INTEGRAL (Chernyakova et al. 2004). The only mention of this source in the literature before the observations reported here (besides the ROSAT catalog) can be found in Kaspi et al. (1995). In this paper the authors report results of ASCA observations of the famous binary system PSR B1259-63, and mention the presence of the another source located only 10 arc-minutes away to the north-west. Kaspi et al. (1992) note, in particular, that the absorption column \( N_H \) in the direction of this source is higher than that of PSR B1259-63, and that during their observations the brightness of 2RXP J130159.6-635806 was smaller, but comparable to that of PSR B1259-63.

We started to follow the source after its detection with INTEGRAL and our first XMM-Newton observation in a set of observations organized to monitor PSR B1259-63 during its 2004 periastron passage (PSR B1259-63 has a very long, 3.4 years, orbital period). Analyzing these observations we have noticed that 2RXP J130159.6-635806, which was also in the field of view, was significantly brighter than it was during the ASCA observations (Chernyakova et al. 2004). On January 24, 2004 the 1-10 keV intensity was found to be approximately an order of magnitude higher than during the ASCA observation performed on August 13, 1995.

In 2001 – 2004 PSR B1259-63 was regularly monitored by XMM-Newton and 2RXP J130159.6-635806 was always in the XMM-Newton field of view. In this paper we present the analysis of all available X-ray data from ASCA, BeppoSAX, INTEGRAL, and XMM-Newton in order to understand the nature of this variable source and investigate its properties. In particular, using the XMM-Newton data

2 OBSERVATIONS AND DATA ANALYSIS

2.1 INTEGRAL observations

Since the launch of INTEGRAL (Winkler et al. 2003) on October 17, 2002, 2RXP J130159.6-635806 was several times in the field of view of the main instruments during the routine Galactic plane scans and pointed observations (see Table 1 for details). Most of the times the distance of the source from the center of the field of view was too big, and the exposure too short to use either the X-ray monitor JEM-X, or the spectrometer SPI. Therefore IBIS/ISGRI (Lebrun et al. 2003) is the only instrument we can use in our analysis of this source. In this analysis we have used the version 4.2 of the Offline Science Analysis (OSA) software distributed by ISDC (Courvoisier et al. 2003).

In 2003 the source was only marginally detected with IBIS/ISGRI, while in the beginning of 2004 it was clearly seen in the 20–60 keV energy range. To obtain better results for spectral analysis we have combined data obtained on January 26 and February 7, when source was the brightest.

2.2 XMM-Newton observations

In the course of monitoring of PSR B1259-63, XMM-Newton observed 2RXP J130159.6-635806 10 times during 2001 – 2004, see Table 2 for the journal of the observations. These data are a combination of public and private observations. The Observation Data Files (ODFs) were obtained from the online Science Archive2, and were then processed and filtered using xmmselect within the Science Analysis Software (SAS) v6.0.1. In all the observations the source was observed with MOS1 and MOS2 detectors only. The 2001 – 2003 observations (X1 – X5) were done in the Full Frame Mode, while the 2004 observations were performed in the Small Window Mode, in order to minimize pile-up problems for the primary source PSR B1259-63. In all observations a medium filter was used.

The spectra and light curves were extracted from a 35″ radius circle around the source position for the weak state of the source (i.e. obs. X1 – X5, X9, X10), and from a 50″ radius circle for the outburst phase (obs. X6 – X8). As 2RXP J130159.6-635806 was not a primary goal of the XMM-Newton observations its position is shifted to the edge of the field of view, and the shape of the source is slightly elongated. Therefore, in order to avoid mixing of source and background photons for the weak states of the source, we collected background light curves and spectra from a 35″ radius circle located close to the source. For the bright state of the source we have used a circle of larger radius, and collected background light curves and spectra from a 100″ outer radius annulus centered on the source position.

Obs. X2, X4, X6 and X9 were partially affected by soft proton flares. Since proton flares originate from the interaction of the soft protons in the Earth’s magnetosphere with the telescope, their timing behaviour is supposed to have no periodic structure. Therefore, no filtering of the data was applied to the timing analysis, as was done for another new X-ray pulsar IGR/AX J16320-4752 (Lutovinov et al. 2005a). We have nevertheless eliminated obs. X4 and X9 from our study as in these data sets the influence of the soft proton flares was especially strong. Arrival times of the photons have been corrected to the Solar System barycenter. The pulse period was searched with the epoch folding technique (Leahy et al. 1983): we produced periodograms and derived the best-fit period for each data set. Ten bins per any trial period were used. For the determination of the uncertainty of the source period we used the bootstrap method. We simu-

2 http://xmm.vilspa.esa.es/external/xmm_data_acq/xsa/index.shtml
lated a number of source “fictional” lightcurves, generating randomly (in accordance with the poissonian statistics of the counts) its flux in each lightcurve bin. These lightcurves provided us the range of “best-fit” periods of the source pulsations, therefore giving us information about the period uncertainty. Errors given in the paper represent a 1σ confidence level.

For the spectral analysis the periods of soft protons need to be filtered out. To exclude them we extracted light curves above 10 keV with a hundred second binning and excluded all time bins in which the count was higher than 1.5 cnt/s.

Data from MOS1 and MOS2 detectors were combined in both timing and spectral analysis in order to achieve better statistics.

2.3 ASCA observations

2RXP J130159.6-635806 was in the ASCA field of view during the dates listed in Table 2. In our subsequent analysis we have used the data of both Gas Imaging Spectrometers (GIS 2 and 3). The data were analyzed with the help of the standard tasks of LHEASOFT/FTOOLS 5.2 package in accordance with the recommendations of the ASCA Guest Observer Facility.

2.4 BeppoSAX observations

During 1997 2RXP J130159.6-635806 was several times within the field of view of the instruments of the BeppoSAX observatory. Unfortunately flux of the source detected by the MECS telescopes was strongly contaminated by instrumental features (e.g. “strongback”, see Boella et al. 1997), and therefore detailed analysis of the source spectrum is not possible. However, the data obtained can still be used for timing analysis. For the data reduction we used standard tasks of LHEASOFT/FTOOLS 5.2 package. We only present here the results of an observation performed on September 8, 1997, when the statistics was good enough to perform a pulse search.

3 RESULTS

3.1 Imaging Analysis

In Figure 1 a zoom of the mosaic of all the INTEGRAL observations mentioned in Table 1 is given. 2RXP J130159.6-635806 is clearly seen in the image, along with a new source IGR J12349-6434 we have found during our analysis (Chernyakova et al. 2005a). All sources shown in the image were taken into account for a proper analysis of INTEGRAL data (Goldwurm A. et al., 2003).

During the XMM-Newton monitoring programme of PSR B1259-63, two sources were clearly detected (e.g. Fig. 2 represents the contour plot of Obs. X6). Besides PSR B1259-63 itself a second source can clearly be seen. The best coordinates we derive are RA J2000 = 13h01m58s.8, DEC J2000 = -63°58′10″ (the conservative error estimation is 3″). This position is about 6″ from the best ROSAT position of 2RXP J130159.6-635806. The uncertainty of the localisation of 2RXP J130159.6-635806 with ROSAT is 5″ (ROSP-SPC catalog3), therefore we conclude that most likely XMM-Newton source and the ROSAT one are the same.

3.2 Spectral Analysis

The 1993–2004 time history of the 2 – 10 keV flux from 2RXP J130159.6-635806 as observed by ASCA and XMM-Newton is shown in the upper panel of Fig. 3. While during the ASCA and the first half of the XMM-Newton observations (X1 – X5) the flux of the source was practically constant at a value ~ 2.5 × 10⁻¹¹ ergs cm⁻² s⁻¹, an outburst can be seen between the end of January and the beginning of February 2004 (obs. X5 – X10). During this period the

3 ftp://ftp.xray.mpe.mpg.de/rosat/catalogues/2rxp/pub
source flux increased by a factor of more than 5. Due to the strategy chosen for the PSR B1259-63 monitoring campaign, the whole outburst was not entirely covered. During the flare 2RXP J130159.6-635806 was observed only twice (24 Jan and 10 Feb), with approximately the same flux level. During the following 10 days its flux dropped to the 2001-2003 level with a characteristic decay time of \( \sim 7 \) days (Fig. 3).

As can be seen from Table 1, this outburst was also detected by INTEGRAL in the 20 – 60 keV energy range. While in 2003 out of a \( \sim 260 \) ks observation, the source was only marginally detected at \( \sim 3 \)σ level, it was clearly seen during a 6.1 ks observation on January 26, 2004 (I3), and during a 4.2 ks observation on February 7, 2004 (I4). At those times it was ten times brighter than its averaged level over 2003. On February 19, 2004 (I5) and during a ToO observation of PSR B1259-63 performed in March 2004 (Shaw et al. 2004), the source was again only marginally or not detected.

The spectral analysis was done with the XSPEC software package. The spectrum of 2RXP J130159.6-635806 during the lowest state as observed with ASCA in 1994 (obs. A4), a typical XMM-Newton spectrum of the source in 2002 – 2003 (obs. X3), XMM-Newton and INTEGRAL spectra during the outburst (obs. X7, obs. I3+I4) and just after (obs. X8), are shown on Fig. 4.

The \textit{XMM-Newton} and ASCA data show that the spectrum of the source in the soft \( 2 – 10 \) keV energy range is well described by a simple power law modified by absorption. In Table 3 we present results of three-parameter fits. The uncertainties are given at the 1σ level. The following analysis showed that such variations are also observed in the light curve of the source in low state.

![Spectral evolution of 2RXP J130159.6-635806](image)

For all observations, the value of the photo-absorption is practically constant with an average value of \( N_H = (2.48 \pm 0.07) \times 10^{22} \text{cm}^{-2} \). This value is about five times higher than the value we found for PSR B1259-63 \( (0.48 \pm 0.03 \times 10^{22} \text{cm}^{-2}) \), which is located only 10 arcminutes away (Chernyakova et al., 2005b). Measurements of the interstellar hydrogen in the Galaxy by Dickey & Lockman (1990) give \( N_H \) values in the range \( (1.7 – 1.9) \times 10^{22} \text{cm}^{-2} \), which is smaller than the one we deduced from X-ray spectral fits. This indicates that part of the absorption might be intrinsic to the source.

While the ASCA and XMM-Newton data are well fitted with a simple power law modified by photo-absorption (see Table 3), INTEGRAL data show a presence of a high-energy cut-off at \( \sim 25 \) keV which is typical for accreting X-ray pulsars (White et al. 1993). We fitted the joint spectrum obtained with XMM-Newton (X7) and INTEGRAL (I3+I4) with an absorbed cut-off power law. The best fit parameters obtained are: \( N_H = (2.55\pm0.13) \times 10^{22} \text{cm}^{-2} \), \( \Gamma = 0.69\pm0.05 \), \( E_{cut} = 24.3\pm3.4 \text{keV} \), \( E_I = 8.5\pm3.3 \text{keV} \). The normalization of the INTEGRAL/IBIS spectrum was taken as arbitrary.

### 3.3 Timing Analysis

Analyzing the light curve of 2RXP J130159.6-635806 obtained with XMM-Newton in the bright state we find that it demonstrates near coherent strong variations with a characteristic time about 700 s. Fig. 5 (upper panel) shows the example of a \( 48 \) s – binned \( 2–10 \) keV MOS1 background subtracted light curve of 2RXP J130159.6-635806 during the flare (obs. X6). The periodograms (\( \chi^2 \) distribution versus trial period for observations X3 and X6) are also represented in the same figure. Periodic variations of the source flux are obvious. The following analysis showed that such variations are also observed in the light curve of the source in low state.

Subsequent analysis of ASCA and \textit{BeppoSAX} light

* in $10^{-11}$erg cm$^{-2}$ s$^{-1}$ units.

Figure 5. MOS1 $2-10$ keV light curve of 2RXP J130159.6-635806 during the flare (obs. X6) (top panel), and $\chi^2$ distribution versus trial period for the brightest (X6) and the longest (X3) observations (middle and bottom panels respectively).

Curves of the source flux also showed pulsations, although not in all the datasets. This is due to the much smaller statistics of these data. With INTEGRAL data we can set only upper limit on the pulse fraction. For the brightest I3 and I4 observations the 3σ upper limit is 70%, which is consistent with almost simultaneous XMM-Newton observations X6 and X7.

The values of the pulse period obtained between 1994 and 2004 are given in Table 4 and Fig. 6. An average spin up rate changes from $\dot{P} \simeq -6 \times 10^{-8}$ s$^{-1}$ in 1994–2001, to approximately $\dot{P} \simeq -2 \times 10^{-7}$ s$^{-1}$ in 2001–2004, that corresponds to $\dot{\nu} \simeq 10^{-13}$Hz s$^{-1}$ and $\dot{\nu} \simeq 4 \times 10^{-13}$Hz s$^{-1}$ respectively.

Figure 6. Time evolution of 2RXP J130159.6-635806 pulse period.

Figure 7. 2RXP J130159.6-635806 pulse profiles variations in the $2-10$ keV energy range. Pulse profiles have been aligned using the minimum phase bin.
The pulse fraction for the bright state of the source (obs. X6) was measured to be 35 ± 6%, which is close to the 30 ± 2% reported in previous studies. The 2–10 keV pulse profiles of 2RXP J130159.6-635806 during the brightest observation (X6) along with the hardness ratio.

The 2–10 keV pulse profiles of 2RXP J130159.6-635806 obtained in each data set by folding of the XMM-Newton light curves at the best fitted period are shown in Fig. 7. In general the source pulse profile consists of one broad peak, but in several observations (the low intensity ones) some additional features (as a second peak) are visible. We have calculated the 2

In order to study the reasons of the variations in the shape of the pulse profile, we extracted separately spectra of obs. X6 from the low phase and from high phase. The background spectra were extracted from the same GTIs, and response files were produced as explained in Section 2.2. We then fitted the resultant spectra in XSPEC with a simple model of an absorbed power law. The best fit parameters are $N_H = 2.2 \pm 0.3 \times 10^{22} \text{ cm}^{-2}$, and $\Gamma = 0.38 \pm 0.14$ with a 2-10 keV unabsorbed flux of $6.9 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ for the low phase, and $N_H = 2.19 \pm 0.12 \times 10^{22} \text{ cm}^{-2}$, and $\Gamma = 0.56 \pm 0.05$ with a 2-10 keV unabsorbed flux of $1.5 \times 10^{-11} \text{ erg cm}^{-2} \text{ s}^{-1}$ for the high phase. In both cases the reduced $\chi^2$ is close to 1. The $\Gamma-N_H$ contour plots for both phases are given on Fig. 8. It is clear that the variations between both phases are not due to variations of the absorbing column density. On the contrary they seem to reflect some changes in the spectral properties of the emitting medium, since there is some increase in the photon index. However at the 3σ level both values are still compatible.

We investigated the energetic dependence of the pulse fraction for the bright state of the source (obs. X6) and found that it is more or less stable around 53–55% in the 2–4 keV band.

### 4 OPTICAL COUNTERPART AND THE SOURCE DISTANCE

The accretion powered X-ray pulsars are usually found within high-mass X-ray binaries (HMXB). The HMXB may be divided mainly into those with main-sequence Be star companions, and those with evolved OB supergiant companions.

In the case of Be/X-ray binaries the hard X-ray emission is caused by accretion of circumstellar material on to the neutron star. The source of accreting material is thought to be concentrated towards the equatorial plane of the rapidly rotating Be stars. Most of Be/X-rays binaries are transients, displaying X-ray outburst and long period of quiescence, when no X-ray flux is detected. A smaller group of Be/X-rays binaries are persistent sources with rather low X-ray luminosity ($< 10^{35} \text{ erg/s}$), relatively long ($> 200 \text{ s}$) pulse pe-
periods and very weak iron line at 6.4 keV. (Reig & Roche, 1999, Negueruela 2004, Haberl & Pietsch 2004).

The supergiant binaries may be further subdivided into two classes, depending on whether the mass transfer is due to the Roche lobe overflow, or a capture from the stellar wind. As the typical spin period for the pulsars with the companions filling its Roche lobe is less than 20 seconds (e.g. Corbet 1986) such a companion seems to be unlikely for 2RXP J130159.6-635806. The wind-fed supergiant binaries has long (of several hundreds seconds) spin period, and are persistent sources with short, irregular outbursts(e.g. Corbet 1986, Bildsten et al. 1997, Negueruela 2004). All the known systems display approximately the same X-ray luminosity \( \sim 10^{36} \) erg/s. Variable X-ray activity of 2RXP J130159.6-635806 indicates that this binary system unlikely contains an OB supergiant.

In any of the cases mentioned above we should expect that the optical companion of the X-ray source should be bright in the optical and infrared spectral bands. In order to check this we used the results of DSS and 2MASS surveys. In both catalogs a relatively bright star with magnitudes \( B = 17.2, R = 13.9, J = 8.87, H = 7.53, K = 7.01, \) is visible in the vicinity of the X-ray source, but its position is just outside the XMM-Newton error box (the offset between the positions is \( \sim 4.4'' \)). Besides this bright star another possible counterpart candidate is found in 2MASS with coordinates (equinox 2000) RA=13h01m58.7s, DEC=+63°58′09″ (at \( \sim 1.1'' \) from the best XMM-Newton position) and magnitudes \( J = 12.96 \pm 1.33, H = 12.05 \pm 0.03, K_s = 11.35 \pm 0.09 \). The good agreement between both positions would tend to suggest that this second source is the likely counterpart to 2RXP J130159.6-635806.

To estimate the de-reddened magnitude we assume that this counterpart was only absorbed by the Galactic absorption on the line of sight. Using the value of \( N_H = 1.7 \times 10^{22} \, \text{cm}^{-2} \) we estimate the de-reddened magnitudes \( J_{drc} = 10.73 \pm 1.33, H_{drc} = 10.72 \pm 0.03, K_{drc} = 10.51 \pm 0.09 \) (only statistical uncertainties are quoted). If the companion star is a Be main sequence star with surface temperature around 10000 K and the radius around 6-10 \( R_\odot \), we can expect to see its infrared brightness \( J, H, K \sim 10 - 11 \) if the binary system is at the distance \( \sim 4 - 7 \) kpc. An additional tentative argument in favour of such source distance is the source location in the direction to the Crux spiral arm tangent, as HMXBs are concentrated towards galactic spiral arms (Grimm et al. 2002, Lutovinov et al. 2005). At such a distance an unabsorbed intrinsic luminosity of 2RXP J130159.6-635806 is about \( \sim 5 \times 10^{34} - 10^{35} \) erg/s, i.e. compatible with the typical luminosities of the persistent Be/X-rays binaries.

5 CONCLUSIONS

We report the identification by XMM-Newt on of a new X-ray pulsar with a spin period of \( \sim 700 \) s in the region of the Crux spiral arm. The source was observed several times in 1993-2004 with ASCA, BeppoSAX and XMM-Newt on during the monitoring campaigns of the pulsar PSR B1259-63. The typical flux measured from the source in the 2 – 10 keV energy band is about \( (2 - 3) \times 10^{-11} \, \text{erg cm}^{-2} \, \text{s}^{-1} \), but in Jan-Feb 2004 an outburst with more than 5 times increase of the intensity was observed from the source. During this outburst the source was also detected in the hard X-rays with the INTEGRAL observatory. Strong pulsations of the X-ray flux with a period \( \sim 700 \) s were detected. The study of a set of observations has shown that the pulse period changed from \( \sim 735 \) sec in 1994 to \( \sim 704 \) sec in 2004. The average value of the spin-up rate is \( \dot{\nu} \approx 2 \times 10^{-13} \, \text{Hz s}^{-1} \), that is typical for accretion powered X-ray pulsars (see e.g. Bildsten et al. 1997). Long pulse period indicates that the pulsar likely resides in a binary system with a massive companion. The proposed infrared counterpart to the X-ray source does not contradict this hypothesis. From brightness of the infrared counterpart measured, a tentative estimate of the distance of binary system is 4-7 kpc, which can indicate that the HMXB is located close to the Crux spiral arm tangent.

6 ACKNOWLEDGEMENTS

The authors acknowledge useful discussions with T.J.-L. Courvoisier, P. Hakala, A. Paizis, I. Kreykenbohm, S.E. Shaw, and thank L. Sidoli for valuable comments on the details of BeppoSAX data reduction. Authors are grateful to L. Foschini for the helpful advises on the XMM-Newton data analysis. Authors thank S. Molkov for the support of this work. Authors are grateful to the anonymous referee for helpful comments. This work was partially done during AL visits to the INTEGRAL Science Data Centre. AL thanks the ISDC staff for its hospitality and computer resources; these visits were supported by ESA. AL also acknowledges the support of RFFI grant 04–02–17276.
