INTRODUCTION

The administration of adrenaline to resolve anaphylactic shock may be insufficient in patients taking oral beta-blockers (Lang, 1995). Additionally, adrenaline or anaphylaxis chemical mediators increase the risk of myocardial infarction (MI), referred to as Kounis syndrome (Kounis, 2016). Prior reports comprised 235,420 allergy patients have found a 1.1% prevalence and 7.0% inhospital mortality (Desai et al., 2019). Kounis classification has three variants: type 1, coronary spasm; type 2, coronary thrombus due to atherosclerotic plaque disruption and thrombus aggregation; and type 3, stent thrombosis/restenosis (Abdelghany et al., 2017).

CASE REPORT

The patient was a 71-year-old male with a history of allergy to mackerel. Having worked as a landscaper for 20 years, however, he had no history of bee allergy. On a morning in August 2020, at 9:00 a.m., he began lawn mowing and was attacked by bees that stung him on the left lower eyelid, anterior forehead, left upper lip, and right dorsal hand. A colleague soon noticed his loss of consciousness and immediately called in the emergency.

Upon on-site arrival (Figure 1, left), the vital signs were as follows: Japan coma scale 1, Glasgow coma scale 4–5–6, blood pressure 60 mmHg, heart rate 99bpm (regular), respiratory rate 30/min, oxygen saturation 90%, and pupil size 3 mm/3 mm with normal light reflex. General respiratory sounds were faint, although wheezing and rale were noted. The extremities were moist, and a rash with itching was present on the abdominal skin. The emergency dispatch physician administered 0.3 mg adrenaline intramuscular injection (i.m.) twice for the prolonged shock.

The patient was transferred to the emergency department, but the hypotension returned. The third 0.3 mg adrenaline i.m. was administered, followed by intravenous administration of famotidine, dexchlorpheniramine maleate, and hydrocortisone.

Should beta-blockers be continued as a treatment for myocardial infarction in the case of kounis syndrome?

Abstract

A 71-year-old male patient reported to our hospital with anaphylactic shock, and the following two issues were focused in this case. First, he was resistant to adrenaline because of taking beta-blocker, and shock was repeated until glucagon administration was initiated. Second, he developed acute coronary syndrome. Two mechanisms contributing to Kounis syndrome were differentiated: 1) adrenaline induced coronary spasm and platelet activation or 2) a mismatch between oxygen supply and demand due to an allergic reaction. Beta-blocker therapy was discontinued because his cardiac function was preserved. Secondary preventive beta-blockers in recovering myocardial infarction with severe anaphylaxis history should be carefully considered.

sodium succinate. Cold sweats and nausea were detected, and the patient lost consciousness again. At this point, we discovered that he had taken oral agents, bisoprolol (2.5 mg), azilsartan (40 mg), and amlodipine (10 mg), due to previous abdominal aortic dissection and hypertension. Therefore, we immediately administered 1 mg of glucagon intravenously slow injection, after which consciousness was rapidly regained. After admission to the intensive care unit, no anaphylaxis relapses occurred, and the skin symptoms improved.

Time-course electrocardiographs (ECGs) are shown in Figure 2. A normal finding was observed on ECG-1. However, after adrenaline administration, lead III in ECG-2 revealed a q wave plus low QRS voltage and 1 mm of ST elevation, low QRS voltage in V1-V6, and a tendency toward prolonged QT intervals. Follow-up blood tests showed a significant increase in cardiac enzymes (Table 1). Since the patient had no chest symptoms and preserved ejection fraction (EF 60%), and the golden time passed for percutaneous coronary intervention (PCI), conservative treatments were selected. ECGs showed various changes afterward (Figure 2), and elevated enzymes persisted until at least day 6 (Table 1).

A coronary computed tomography scan on day 5 revealed stenosis of the left anterior descending (LAD) coronary artery (Figure 3a); therefore, PCI was enforced for segment 6 on day 13 (Figure 3b). Nitrite and antiplatelet agents were administered, and calcium antagonist was increased to the maximum dose instead of beta-blockers for control in both MI and blood pressure. An 123I-metaiodobenzylguanidine nuclear medicine study (123I-MIBG; Fuji Film RI Pharma, Tokyo, Japan), which evaluated sympathetic nerve denervation, revealed reduced uptake at the wall anteroinferior to the apex at day 30 (Figure 3c). Analysis of the patient’s heart rate variability using high-resolution ambulatory ECG showed vagal hyperactivity while awake and relative sympathetic hyperactivity while asleep, thereby indicating autonomic circadian disorder (Figure 3d).

### DISCUSSION

The two main considerations in this case were as follows: 1) the impact of adrenergic sensitivity on anaphylaxis against a backdrop of oral beta-blocker therapy and 2) the necessity of beta-blockers during the chronic phase in patients with Kounis syndrome.

First, oral beta-blockers reportedly blunt the physiological responses of beta-receptors to catecholamine, and furthermore, the stimulation of alpha- and beta-adrenergic receptors by adrenaline tend toward relatively alpha-stimulation and increases the risk of both severe bradycardia and cardiac arrest (Lang, 1995). In adrenaline-refractory cases, the use of glucagon is appropriate because it increases the concentration of cyclic adenosine

monophosphate in the myocardium without β-receptor involvement (Figure 4a). However, it should be noted that rapid bolus injection may induce vomiting, so patients with consciousness disturbance should be airway secured in the supine position. In addition, the drug for lifesaving in anaphylaxis can be induced anaphylaxis. Sodium metabisulfite is commonly used as an antioxidant in the food and pharmaceutical industries, and every commercially available adrenaline contains sodium metabisulfite (Kounis et al., 2020). Metabisulfite developed urticaria, angioedema, and nasal congestion through an IgE-mediated mechanism (Sokol & Hydick, 1990), increased discomfort during injection of lidocaine added with adrenaline (Campbell et al., 2001), and induced anaphylactic shock during the administration of epidural anesthesia for cesarean sections (Soulat et al., 1991).

Second, ACS in the present case probably developed within a brief time after the second administration of adrenaline. Adrenaline sometimes stimulates a potent coronary spasm (Ferry et al., 1986), and secondary promotes platelet activation via sympathetic stimulation (Table 2) (Larsson et al., 1989; Laustiola et al., 1986; Wallén et al., 1999). Adrenaline also induced autonomic imbalance in the Figure 4b. In this case, the patient's heart rate was 99 bpm before adrenaline intramuscular administration, which reduced it to 70 bpm. Increasing cardiac rate by β1 stimulation was not observed. Therefore, adrenaline appears less likely to be the cause

of the coronary spasm. However, at the recognition of the second shock, the possibility of Kounis type I should have been considered, and the third adrenaline administration should have been avoided.

As another mechanism of ACS, allergic biological reactions cause increased eosinophils and mast cells in cardiac tissue (Kounis, 2016), which leads to hypercoagulation (Figure 4b). Large amounts of released cytokines, histamine, and platelet-activating factor by degranulation from mast cells directly damage the vascular endothelium and increase vascular permeability through dynamic migration, which results in an imbalance between intercellular and intravascular plasma volume (Varricchi et al., 2019). These mechanisms differ from those of plaque destruction observed in common MI (Thygesen et al., 2018). In this patient, significant stenosis in the proximal LAD region and persistent severe hypotension might have induced a mismatch between coronary oxygen supply and demand; diagnosis of Kounis type II may be appropriate (Figure 4b).

The Japanese Circulation Society Guidelines 2018 recommend that long-term oral beta-blocker therapy is needed for MI patients with heart failure or reduced EF (Kimura et al., 2019). In contrast, it is not mandatory in our country for preserved EF patients because of the high rate of PCI. Randomized clinical trials comparing beta-blockers and Ca antagonists (JBCMI) (JBCMI Investigators, 2004) or comparing carvedilol-treated and non-treated patients (CAPITAL-RCT) (Watanabe et al., 2018) showed no significant difference in the incidence of cardiovascular death and reinfarction between groups. Contraindications to beta-blockers were present; Ca antagonist or no medication may be a substitute option.

4 | CONCLUSION

In this patient with preserved EF, Ca antagonists were the best agents instead of beta-blockers as second prevention plus nitrite and anti-platelet agents. The patient carries a portable adrenaline injection and takes oral antiallergic agents because he intended to resume his landscaping business, whereas patients in whom beta-blockers need to be continued due to low EF should be instructed to carry a drug information booklet to inform the appropriate initial treatment for anaphylaxis (Figure 4b). Insurance reimbursement is currently available for only portable epinephrine injections; however, nasal glucagon will also be hoped to covering by insurance in the future. The most crucial factor that affects the prognosis is close cooperation for the treatments among emergency physicians' management for anaphylactic shock (Figure 4a), cardiologists' assessment of beta-blocker administrations (Figure 4b), and allergists' preventive care for allergies (Figure 4c).
