BACKGROUND: Nonhyperemic pressure ratios (NHPRs) such as instantaneous wave-free ratio, resting full-cycle ratio, or diastolic pressure ratio have emerged as invasive physiologic indices precluding the need for hyperemic agents. The current study sought to evaluate the long-term prognostic implications of NHPRs compared with fractional flow reserve (FFR).

METHODS AND RESULTS: NHPRs were calculated from resting pressure tracings by an independent core laboratory in 1024 vessels (435 patients). The association between NHPRs and the risk of 5-year vessel-oriented composite outcomes (VOCO, a composite of cardiac death, vessel-related myocardial infarction, and ischemia-driven revascularization) were analyzed among 864 deferred vessels. Lesions with positive NHPRs (instantaneous wave free ratio, resting full-cycle ratio, and diastolic pressure ratio ≤0.89) or FFR (≤0.80) showed significantly higher risk of VOCO at 5 years than those with negative NHPRs or FFR, respectively. Discriminant ability for 5-year VOCO was not different among NHPRs and FFR (C-index: 0.623–0.641, P for comparison=0.215). In comparison of VOCO among the groups with deferred concordant negative (NHPRs−/FFR−), deferred discordant (NHPRs+/FFR− or NHPRs−/FFR+), and revascularized vessels, the cumulative incidence of VOCO were 7.5%, 14.4%, and 14.8% (log-rank P<0.001), respectively. The deferred discordant group showed similar risk of VOCO with the revascularized vessel group (hazard ratio, 0.981; 95% CI 0.434–2.217, P=0.964).

CONCLUSIONS: Currently available invasive pressure-derived indices showed similar prognostic implications for vessel-related events at 5 years. Deferred lesions with discordant results between NHPRs and FFR did not show higher risk of vessel-related events at 5 years than revascularized vessels.

Key Words: coronary artery disease □ diastolic pressure ratio □ fractional flow reserve □ instantaneous wave-free ratio □ ischemia □ prognosis □ resting full-cycle ratio

See Editorial by Paul et al.
In the assessment of coronary artery stenosis to guide treatment decision making in the cardiac catheterization laboratory, pressure-derived physiologic indices have been important diagnostic and prognostic tools. Based on numerous clinical publications, fractional flow reserve (FFR)-guided treatment is now regarded as a reference invasive physiologic index. A physiologic index which does not require hyperemia, instantaneous wave-free ratio (iFR), has been introduced and subsequent clinical trials have shown that an iFR-guided strategy was noninferior to a FFR-guided strategy for 1-year clinical outcomes. Further studies evaluated various definitions of pressure-derived indices, such as resting full-cycle ratio (RFR) or diastolic pressure ratio (dPR), and presented identical diagnostic ability among iFR, RFR, and dPR. A later study also presented that these nonhyperemic pressure ratios (NHPRs) have similar diagnostic ability in defining intravascular imaging-defined stenosis severity, in diagnosing positron emission tomography (PET)-defined myocardial ischemia, and share similar prognostic implications for clinical events at 2 years.

Nevertheless, there are no previous reports regarding the long-term prognostic implications of NHPRs. Furthermore, an important issue in daily practice would be the long-term prognosis of deferred lesions with discordant results between NHPRs and FFR compared with revascularized lesions. In this regard, we sought to evaluate the long-term prognosis after deferred revascularization according to NHPRs and comparative prognosis of deferred lesions with discordant results with revascularized lesions.

**METHODS**

Anonymized patient level data will be made available by the corresponding author for reasonable requests. Consent was not obtained for data sharing, but the presented data are anonymized and the risk of identification is minimal.

**Study Design and Patient Population**

The study population was derived from the 3V FFR-FRIENDS study (3-vessel fractional flow reserve for the assessment of total stenosis burden and its clinical impact in patients with coronary artery disease, NCT01621438) and the 13N-ammonia PET registry. The 3V FFR FRIENDS study was a prospective, multinational, and multicenter study which enrolled consecutive patients who were at least 18 years old and had >30% stenosis by visual estimation in major epicardial coronary arteries and underwent successful FFR measurement in 3 major coronary arteries. In the 13N-ammonia PET registry, patients with available 13N-ammonia PET within 3 months of measuring FFR in left anterior descending coronary artery were enrolled.

In both studies, patients with depressed left ventricular systolic function (ejection fraction <35%), acute ST-elevation myocardial infarction within

---

**CLINICAL PERSPECTIVE**

**What Is New?**
- Prognostic implications of nonhyperemic pressure ratios (NHPRs) and fractional flow reserve (FFR) were similar according to binary cut-off values (≤0.89 and ≤0.80, respectively) or as continuous values.
- Positive NHPRs or FFR showed consistently higher risk of 5-year vessel-oriented composite outcome than negative NHPRs or FFR across various subgroups of patient or lesion characteristics.
- Deferred lesions with discordant results between NHPRs and FFR showed higher risk of 5-year vessel-oriented composite outcome than those with concordant negative results; however, it did not show excess higher risk of 5-year vessel-oriented composite outcome than revascularized lesions.

**What Are the Clinical Implications?**
- Any pressure-derived physiologic index, regardless of being nonhyperemic or hyperemic, can be used in the cardiac catheterization laboratory under the same clinical indications.
- Although treatment decision making to revascularize or defer can be made based on 1 physiologic index, simultaneous measurement of both NHPRs and FFR would provide better risk stratification of patients when revascularization is deferred.

---

**Nonstandard Abbreviations and Acronyms**

- %DS: percent diameter stenosis
- dPR: diastolic pressure ratio
- FFR: fractional flow reserve
- iFR: instantaneous wave free ratio
- NHPRs: non-hyperemic pressure ratios
- Pa: proximal aortic pressure
- Pd: distal arterial pressure
- PET: positron-emission tomography
- RFR: resting full-cycle ratio
- VOCO: vessel-oriented composite outcome
72 hours, previous coronary artery bypass graft surgery, chronic renal disease, abnormal epicardial coronary flow (TIMI [thrombolysis in myocardial infarction] flow <3), or planned coronary artery bypass graft surgery after diagnostic angiography were excluded. Total patient population was 1024 vessels (435 patients) and 160 vessels were revascularized. The enrolled patients were included in other published studies. The study protocol was approved by the Institutional Review Board or Ethics Committee at each participating center and all patients provided written informed consent.

**Coronary Physiologic Measurements and Angiographic Analysis**

Coronary angiography was performed using standard techniques. Angiographic views were obtained following the administration of intracoronary nitrate (100 or 200 µg). All angiograms were analyzed at a core laboratory (Seoul National University Hospital) blinded to other data. Quantitative coronary angiography was performed in optimal projections with validated software (CAAS II, Pie Medical System, Maastricht, the Netherlands). Minimal lumen diameter, reference vessel size, and lesion length were measured, and percent diameter stenosis was calculated.

All coronary physiologic measurements were obtained as previously described. Briefly, the pressure-temperature sensor guide wire (Abbott Vascular, Santa Clara, CA, USA) was zeroed and equalized to aortic pressure, and then positioned at the distal segment of a target vessel. Intracoronary nitrate (100 or 200 µg) was administered before each set of physiologic measurements. Resting distal arterial pressure/proximal aortic pressure was calculated as the ratio of mean distal coronary artery pressure to mean aortic pressure in resting state. Continuous infusion of adenosine (140 µg/kg per minute) was used to induce hyperemia. Intravenous infusion of adenosine was maintained until sustained maximal hyperemia and completion of pullback recording. Hyperemic proximal aortic pressure and distal arterial pressure were obtained, and FFR was calculated as the lowest average of 3 consecutive beats during adenosine infusion. After measurements, the pressure wire was pulled back to the guide catheter and the presence of pressure drift was checked. In patients with acute coronary syndrome, physiologic interrogation was performed in non-culprit vessels. Derivations of NHPRs were performed in off-line analysis, as previously described. The iFR was calculated using automated algorithms acting over the wave-free period over a minimum of 5 beats. dPR was also calculated from each individual waveform as an average distal arterial pressure/proximal aortic pressure over the entire period of diastole. The iFR and dPR were calculated using dedicated MATLAB (MathWorks, Inc., Natick, MA, USA). RFR was calculated from each individual waveform using a fully automated off-line software algorithm (RFR release 2.0, Abbott Vascular, Santa Clara, CA, USA). Among the total 1024 pressure tracings, RFR calculation was not possible in 11 vessels due to insufficient quality of resting pressure tracings. All pressure tracings were collected and validated at the core laboratory (Samsung Medical Center) in a blinded fashion.

**Patient Follow-up, Outcome Measurements, and Adjudication of Clinical Events**

Clinical data were obtained at outpatient clinic visits or by telephone contact when needed. An independent clinical events committee whose members were unaware of clinical, angiographic, and physiologic data adjudicated all events. The primary outcome was vessel-oriented composite outcome (VOCO) at 5 years including cardiac death, target vessel-related myocardial infarction and target vessel-related ischemia-driven revascularization. All event records were reviewed to assess vessel-related clinical events and were defined according to the Academic Research Consortium, including the addendum to the definition of myocardial infarction. All deaths were considered cardiac unless an undisputable noncardiac cause was present. Ischemia-driven revascularization was defined as a revascularization procedure for patients with recurrence of angina and positive noninvasive test or positive invasive physiologic test, silent myocardial ischemia proven by positive noninvasive test or positive invasive physiologic test, or acute coronary syndrome with a clear culprit lesion. In order to compare clinical outcomes according to positive or negative pressure derived indices, the cut-off values of ≤0.89 for NHPRs and ≤0.80 for FFR were used.

**Statistical Analysis**

Data were analyzed on a per-patient basis for clinical characteristics and on a per-vessel basis for comparison of lesion characteristics, physiologic indices, and vessel-related clinical outcomes. Among patients who underwent multivessel measurements, the vessel with the lowest FFR value was selected as a representative vessel of that patient for the per-patient analysis. For per-vessel analyses, a generalized estimating equation with an independent correlation structure was used to adjust for intrasubject variability among vessels from the same patient. In comparison of clinical outcomes according to cut-off values of NHPRs and FFR, event rates were calculated based on Kaplan–Meier censoring estimates, and the log-rank test was...
Lee et al. Long-Term Clinical Outcomes of NHPRs

In comparisons of clinical outcomes among groups, a per-vessel comparison of cumulative incidence of target vessel-related events was performed using marginal Cox proportional hazard regression models to calculate hazard ratio (HR) and 95% CI with adjustment for the clustered data. The assumption of proportionality was assessed graphically by log-minus-log plot, and Cox proportional hazard models for all clinical outcomes satisfied the proportional hazards assumption. In order to explore the prognostic implications of invasive physiologic indices as continuous values, estimated VOCO rates at 5 years derived from the marginal Cox proportional hazards regression model were plotted according to invasive physiologic indices. Discriminant ability for the risk of VOCO at 5 years was presented as Harrell’s c-index.

All probability values were two-sided and $P<0.05$ was considered statistically significant.

RESULTS

Patient and Lesion Characteristics

Patient and lesion characteristics of total study population are presented in Table S1. Mean age of population was 63.8±9.7 years and 78.4% were male. Most patients presented with stable angina (87.1%) with intermediate epicardial coronary stenosis (mean percent diameter stenosis of 44.3±17.5%). Among the total 1024 vessels, 160 vessels were revascularized. In comparison of lesion characteristics according to cut-off values of NHPRs and FFR, the lesions with below cut-off value consistently showed significantly worse lesion severity than those with above cut-off value (Table S2).

Comparison of the risk of VOCO at 5 years between positive vs negative (A) iFR, (B) RFR, (C) dPR, or (D) FFR according to their cut-off values. dPR indicates diastolic pressure ratio; FFR, fractional flow reserve; HR, hazard ratio; iFR, instantaneous wave-free ratio; and RFR, resting full-cycle ratio.

J Am Heart Assoc. 2020;9:e016818. DOI: 10.1161/JAHA.120.016818
Clinical Outcomes According to Cut-off Values of Invasive Physiologic Indices

Figure 1 and Table 1 demonstrate vessel-related clinical outcomes at 5 years according to cut-off values of NHPRs and FFR among deferred vessels. Lesions with positive NHPRs (≤0.89) showed significantly increased risk of VOCO compared to those with negative NHPRs (>0.89) (Figure 1A, 1B, 1C, respectively for iFR, RFR, dPR). Classification by FFR showed the same results (Figure 1D). The significant differences in the risk of VOCO were driven mostly by the higher risk of vessel-related ischemia-driven revascularization in lesions with positive NHPRs or FFR (Table 1).

Comparison of Prognostic Implications of Invasive Physiologic Indices

When the associations between NHPRs or FFR with the estimated risk of VOCO at 5 years were evaluated, all invasive physiologic indices showed similar association with the risk of VOCO as continuous values. HR per 0.01 increase of NHPRs or FFR was not different across all the physiologic indices (Figure 2A). Discrimination ability for VOCO at 5 years was not different among iFR, RFR, dPR, and FFR (overall comparison $P=0.215$; Figure 2B).

Influence of Patients or Lesion-Related Factors in Prognostic Implications of Invasive Physiologic Indices

The influence of patient- or lesion-related factors to prognostic implications of NHPRs or FFR was evaluated by subgroup analysis. The higher risk of VOCO in lesions with positive NHPRs or FFR were similarly observed, regardless of patient’s age, sex, presence of diabetes mellitus, target vessels, or location of stenosis in target vessels without significant interactions. In addition, the skewed risk of VOCO in lesions with positive NHPRs or FFR than negative lesions was similarly observed across all the invasive physiologic indices (Figure 3).

Comparative Clinical Outcomes According to Treatment Decision and Invasive Physiologic Indices

In order to evaluate comparative prognosis according to the treatment modality and the discordance or concordance between NHPRs and FFR, the outcomes were compared among the 3 groups: revascularized vessels with positive FFR (revascularized group; n=124), deferred vessels with concordant negative results between NHPRs and FFR (concordant negative group; n=686), and deferred vessels with discordant results between NHPRs and FFR (discordance group;
n=57). In this analysis, 74 vessels with discordant classification among NHPRs were excluded.

Table 2 shows the patient and lesion characteristics among the 3 groups and the revascularized group showed the worst profile of lesion severity. Among the 3 groups, the cumulative incidence of VOCO at 5 years was 14.8%, 14.4%, and 7.5% for the revascularized group, defer with concordant negative group, and defer with discordance group, respectively. Compared with the revascularized group, the concordant negative group showed significantly lower risk of VOCO (HR, 0.478; 95% CI, 0.268–0.852, P=0.012). Conversely, the discordant group showed similar risk of VOCO with the revascularized group (HR, 0.981; 95% CI, 0.434–2.217, P=0.964; Figure 4 and Table 3).

**DISCUSSION**

The current study investigated the prognostic implications of NHPRs including iFR, RFR, and dPR for 5-year vessel-related outcomes. The main findings are as follows. First, prognostic implications of NHPRs and FFR were similar according to binary cut-off values (≤0.89 and ≤0.80, respectively) or as continuous values. Second, positive NHPRs or FFR showed consistently higher risk of VOCO than negative NHPRs or FFR across various subgroups of patient or lesion characteristics. Third, deferred lesions with discordant results between NHPRs and FFR showed higher risk of VOCO than those with concordant negative results. However, deferred lesions with discordant results between NHPRs and FFR did not show higher risk of VOCO than revascularized lesions.

Given the high interindividual variability in estimating angiographic stenosis severity and low diagnostic yield of noninvasive stress tests for myocardial ischemia,18,19 invasive physiologic indices-based treatment decision making has been the standard to define functionally significant epicardial coronary stenosis in the cardiac catheterization laboratory.20 Despite ample evidence supporting its clinical relevance and prognostic benefit over angiography-only based treatment, the adoption rate of FFR-guided strategy remains low and variable.21 As there is no need for hyperemia and related medical costs, NHPR
has the potential for raising the adoption rate of physiologic indices-guided strategy in daily practice. Landmark trials demonstrated similar 1 year clinical outcomes following iFR-guided strategy versus FFR-guided strategy and both indices have been recommended at an equivalent level. After introduction of iFR, pressure-wire manufacturers developed their own NHPRs with slightly different definitions, such as RFR or dPR. Previous studies support that those NHPRs share similar diagnostic performance for intravascular imaging-defined anatomic stenosis severity, inducible myocardial ischemia defined by independent reference tests, and prognostic implications. However, the long-term prognosis of NHPR-guided clinical decision making has not yet been evaluated. As NHPRs and FFR possess different conceptual bases and evaluate different aspects of the coronary circulation, it is essential to evaluate their long-term prognostic implications. The current study reported the association between 5-year vessel-related events and invasive physiologic indices, and showed both NHPRs and FFR share similar risk stratification ability according to their current cut-off values. These pressure-derived indices, regardless of measurement conditions (nonhyperemic versus hyperemic), showed similar association with the risk of VOCO as continuous values and also shared similar discriminant ability. In addition, positive NHPRs or FFR showed consistently higher risk of VOCO than negative NHPRs or FFR across various subgroups of patient or lesion characteristics. These results imply that the important issue may not be which index to choose, but rather how to increase the rate of its use in daily practice.

Another important question is how to interpret and treat the discordant results between NHPRs and FFR. In this study, the discordance among different NHPRs was found in only 74 vessels out of 1024 vessels (7.2%). Previous studies showed that discordance among different NHPRs does not have prognostic significance. For discordance between NHPRs and FFR, previous studies showed that only lesions with concordant abnormal results in both NHPRs and FFR showed significantly increased risk of VOCO at 2 years or patient-oriented composite outcome at 5 years. These previous studies suggested the lack of difference in clinical outcomes between 2 types of discordance (NHPRs−/FFR+ or NHPRs+/FFR−). In the current study, the vessel-related outcomes were compared with revascularized
lesions using 5-year outcome data. The deferred lesions with concordant negative results (NHPRs–/FFR–) showed lower risk of VOCO than the other groups. However, deferred lesions with discordant results between NHPRs and FFR showed similar risk of VOCO with revascularized lesions up to 5 years of follow-up. These results imply that there might be a risk continuum from concordant negative to concordant abnormal lesions, and the lesions with abnormal results in 1 of the physiologic indices might have that risk profile between them. The lack of difference in the risk of VOCO between deferred discordant lesions and revascularized lesions support the safety of deferral of revascularization for lesions with discordant results. However, the possibility of late vessel-related events of those lesions and higher incidence of discordance in left anterior descending artery, which usually has the largest subtended myocardium, warrants meticulous follow-up with intensive medical treatment for patients with discordant results among the physiologic indices.

The current study results imply two clinical implications in daily practice. First, any pressure-derived physiologic index, regardless of being nonhyperemic

| Resting full-cycle ratio (RFR) | 0.79±0.16              | 0.97±0.03                 | 0.90±0.04        | <0.001  |
| Diastolic pressure ratio (dPR) | 0.80±0.15              | 0.97±0.03                 | 0.91±0.04        | <0.001  |
| Fractional flow reserve (FFR)  | 0.67±0.10              | 0.92±0.06                 | 0.80±0.04        | <0.001  |

Values are mean±SD, median (interquartile ranges, 25th–75th), or n (%). MI indicates myocardial infarction; PCI, percutaneous coronary intervention; and SYNTAX, Synergy between PCI with Taxus and Cardiac Surgery score.

*Among the total 1024 vessels, 74 vessels with discordance among NHPRs, 53 vessels with deferred revascularization despite concordant abnormal results in both NHPRs and FFR, 11 vessels with unavailable RFR, and 17 vessels which were revascularized despite FFR >0.80 were excluded from this analysis.
or hyperemic, can be used in the cardiac catheterization laboratory under the same clinical indications. Different nomenclature or definition of each index or unavailability of 1 specific vendor’s console should not be a hurdle in applying the physiology-guided strategy in clinical practice. What is more important is not which index should be used, but rather there be standardization of measurement protocol and assurance of the accuracy of measurement. Second, although treatment decision making to revascularize or defer can be made based on 1 physiologic index, simultaneous measurement of both NHPRs and FFR would provide better risk stratification of patients when revascularization is deferred. In patients with discordant results between NHPRs and FFR, continued efforts including meticulous medical treatment and secondary prevention are warranted.

Limitations

Some limitations should be acknowledged. First, NHPRs were calculated off-line in an independent physiology core laboratory. Second, the decision for revascularization of the target lesion was mainly made based on FFR value, and not on NHPRs. Third, comparison of NHPR-guided versus FFR-guided strategy in specific patient subsets could not be performed, because the current study was not randomly allocated into two different strategies. Fourth, participating investigators were not blinded to the physiologic

Figure 4. Comparison of 5-year clinical outcomes classified by NHPRs and FFR.

The cumulative incidence of VOCO at 5 years are compared among revascularized vessels, deferred vessel with concordant negative results in both NHPRs and FFR, and deferred vessel with discordant results between NHPRs and FFR (NHPR−/FFR+ or NHPR+/FFR−). FFR indicates fractional flow reserve; HR, hazard ratio; NA, not available; NHPRs, nonhyperemic pressure ratios; and VOCO, vessel-oriented composite outcomes.
indices, and this might have influenced their management strategies for these patients. Nevertheless, all clinical events were independently adjudicated by the clinical events adjudication committee. Fourth, the current study population had relatively low clinical and anatomical risk. Fifth, the number of deferred lesions with discordant results between NHPRs and FFR was relatively small. Similarly, the number of revascularized lesions was relatively small. In addition, the overall cumulative incidence of events was relatively low during the 5-year follow-up period. In this regard, further investigations with more participants and a longer follow-up period are needed. Sixth, because this was not a randomized controlled trial, possibility of selection bias or unmeasured confounders should be considered in interpreting the results. Seventh, the iFR and dPR values used in the current study were calculated using off-line software. Because the manufacturers of iFR and dPR did not publicly share information about cycle window, cycle landmark detection, cycle filtering, and cycle averaging, these values might not be essentially the same values as the commercialized indices.

CONCLUSIONS

Currently available invasive pressure-derived indices showed similar prognostic implications for vessel-related events at 5 years. Deferred lesions with discordant results between NHPRs and FFR did not show higher risk of vessel-related events at 5 years than revascularized vessels.

Table 3. Comparison of Clinical Outcomes at 5 Years Among Revascularized Vessels, Concordant Negative Defer, and Discordant Defer Groups According to Nonhyperemic Pressure Ratios and Fractional Flow Reserve*

|                             | Revascularized Vessels | Concordant Negative Defer | Discordant Defer | P Value |
|-----------------------------|------------------------|----------------------------|------------------|---------|
| Per-vessel analysis (n=869) | 124/869 (14.3%)        | 688/869 (79.2%)           | 57/869 (6.6%)    |         |
| Cardiac death               | 2.5% (3)               | 2.7% (18)                 | 3.6% (2)         | 0.893   |
| Myocardial infarction       | 1.6% (2)               | 1.2% (8)                  | 0.0% (0)         | 0.647   |
| Ischemia driven revascularization | 13.2% (16)         | 5.0% (33)                 | 11.2% (6)        | <0.001  |
| VOCO†                       | 14.8% (18)             | 7.5% (51)                 | 14.4% (8)        | <0.001  |

The cumulative incidence of clinical outcomes is presented as Kaplan–Meier estimates during the median follow-up of 1855.0 days. P values were log-rank or Breslow P value in survival analysis. VOCO indicates vessel-oriented composite outcomes.

†VOCO included cardiac death, vessel-related myocardial infarction, and vessel-related ischemia-driven revascularization.

Values are mean ± SD, median (interquartile ranges, 25th-75th), estimated mean (95% confidence interval) (per-vessel analysis), or n (%).

Generalized estimating equation model or maximum likelihood $\chi^2$ tests were used for overall and between-group comparisons in per-vessel analysis.

† P values for the comparison of variables between high and low iFR groups. ‡ P values for the comparison of variables between high and low RFR groups. * P values for the comparison of variables between high and low dPR groups. § P values for the comparison of variables between high and low FFR groups.

: dPR, diastolic pressure ratio; FFR, fractional flow reserve; iFR, instantaneous wave-free ratio; RFR, resting full-cycle ratio.
