ABSTRACT

We present several different statistical methods to determine the transverse velocity vector of M31. The underlying assumptions are that the M31 satellites on average follow the motion of M31 through space and that the galaxies in the outer parts of the Local Group on average follow the motion of the Local Group barycenter through space. We apply the methods to the line-of-sight velocities of 17 M31 satellites, to the proper motions of the two satellites M33 and IC 10, and to the line-of-sight velocities of five galaxies near the Local Group turnaround radius, respectively. This yields four independent but mutually consistent determinations of the heliocentric M31 transverse velocities in the west and north directions, with weighted averages \( \langle v_W \rangle = -78 \pm 41 \text{ km s}^{-1} \) and \( \langle v_N \rangle = -38 \pm 34 \text{ km s}^{-1} \). The uncertainties correspond to proper motions of \( \sim 10 \mu\text{as yr}^{-1} \), which will be difficult to verify observationally within the next decade. The galactocentric tangential velocity of M31 is 42 km s\(^{-1}\), with 1 \( \sigma \) confidence interval \( V_{\tan} \leq 56 \text{ km s}^{-1} \). The implied M31–Milky Way orbit is bound if the total Local Group mass \( M \) exceeds \( 1.72^{+0.25}_{-0.23} \times 10^{12} \text{ M}_\odot \). If the orbit is indeed bound, then the timing argument combined with the known age of the universe implies that \( M = 5.58^{+0.85}_{-0.72} \times 10^{12} \text{ M}_\odot \). This is on the high end of the allowed mass range suggested by cosmologically motivated models for the individual structure and dynamics of M31 and the Milky Way, respectively. It is therefore possible that the timing mass is an overestimate of the true mass, especially if one takes into account recent results from the Millenium Simulation that show that there is also a theoretical uncertainty of 41\% (Gaussian dispersion) in timing mass estimates. The M31 transverse velocity implies that M33 is in a tightly bound orbit around M31. This may have led to some tidal deformation of M33. It will be worthwhile to search for observational evidence of this.

Subject headings: galaxies: individual (M31) — galaxies: kinematics and dynamics — Local Group

1. INTRODUCTION

The Local Group is dominated by two spiral galaxies, M31 and the Milky Way. These galaxies have comparable properties, with M31 generally believed to be slightly more massive (e.g., Klypin et al. 2002). The next most luminous galaxies, M33 and the Large Magellanic Cloud, are some 10 times fainter (e.g., van den Bergh 2000). The dynamics and future of the Local Group are therefore determined primarily by the relative velocity of M31 with respect to the Milky Way. Unfortunately, this velocity is poorly known. The line-of-sight velocity of M31 can be measured extremely accurately using the Doppler shift of a large variety of tracers. However, even after a century of careful attempts (starting with, e.g., Barnard 1917), still no useful proper-motion measurement exists to constrain the transverse velocity. This limits our ability to answer several fundamental questions. For example, do M31 and the Milky Way indeed form a bound system, as is usually assumed (e.g., van den Bergh 1971)? What is the exact mass of the Local Group implied by the so-called timing argument (e.g., Kahn & Woltjer 1959; Kroeker & Carlberg 1991; Lynden-Bell 1999)? What is the expected future evolution of the M31–Milky Way system (e.g., Cox & Loeb 2008)? And how has the structure of M33 been influenced by possible interaction with M31 (e.g., Loeb et al. 2005, hereafter L05)?

In the present paper we show that it is possible to obtain a statistical determination of the transverse velocity of M31 using the observed velocities of its satellites. The analysis assumes that on average the satellites follow the motion of M31 through space, with some velocity dispersion. The ensemble of line-of-sight velocities, and the individual proper motions available for selected galaxies, then yield independent estimates of the M31 velocity. We also revisit the method previously explored by Einasto & Lynden-Bell (1982), which is based on the assumption that the galaxies in the outer parts of the Local Group follow the motion of the Local Group barycenter through space. We apply the different methods to the currently available data for the relevant Local Group galaxies, and we combine the results to obtain an accurate determination of the M31 transverse velocity. We then use this determination to address the aforementioned questions.

The structure of the paper is as follows. Section 2 discusses the constraints on the M31 transverse velocity, based on the line-of-sight velocities of an ensemble of 17 M31 satellites (\( \S 2.1 \)), the recent high-accuracy proper-motion determinations of the M31 satellites M33 and IC 10 by Brunthaler et al. (2005, 2007) from VLBI observations of water masers (\( \S 2.2 \)), and the line-of-sight velocities of an ensemble of galaxies in the outer parts of the Local Group (\( \S 2.3 \)). The different constraints are compared and combined in \( \S 2.4 \). Section 3 discusses the implications of the inferred M31 velocity for the relative orbit of M31 and the Milky Way (\( \S 3.1 \)) and for the relative orbit of M31 and M33 (\( \S 3.2 \)). Section 4 discusses how the results for the M31 transverse velocity (\( \S 4.1 \)), the total mass of the Local Group as implied by the timing argument (\( \S 4.2 \)), and the Local Group turnaround radius (\( \S 4.3 \)) compare with theoretical predictions and other observational studies. Section 5 presents the conclusions of our work.

In the analysis below we use several coordinate systems. Observational systems have their three principal axes aligned with the line of sight, west, and north directions, respectively, for a
given position on the sky. We also use a galactocentric coordinate system centered on the Milky Way and a barycentric coordinate system centered on the Local Group barycenter. The analysis requires transformations between the positions and velocities in these systems. Many of the necessary notations and derivations can be found in van der Marel et al. (2002; which presents a study of the kinematics of the Large Magellanic Cloud) and are given here without further reference. Heliocentric velocities are generally denoted with a vector $V$, galactocentric velocities with a vector $V$, and Local Group barycentric velocities with a vector $U$. Velocities and proper motions in the observational systems are generally heliocentric (i.e., not corrected for the reflex motion of the Sun), unless stated otherwise.

2. THE M31 TRANSVERSE VELOCITY

2.1. Constraints from Line-of-Sight Velocities of M31 Satellites

The velocity vector of an M31 satellite galaxy can be written as the sum of the M31 velocity vector and a peculiar velocity

$$v_{\text{sat}} = v_{\text{M31}} + v_{\text{pec}}.$$

We assume that any one-dimensional component of $v_{\text{pec}}$ is a random Gaussian deviate with dispersion $\sigma$. More formally, this is true if the velocity distribution of the satellites is both isotropic and isothermal. The first assumption finds some support from studies of galaxy satellite systems (e.g., Kochanek 1996) and clusters of galaxies (e.g., van der Marel et al. 2000). The second assumption is reasonable in view of the fact that the gravitational potentials of dark halos are approximately logarithmic. Either way, in the present analysis there is only a very weak dependence on the accuracy of these assumptions (by contrast to studies of galaxy satellite systems (e.g., Kochanek 1996) and isothermal. The first assumption finds some support from

$$v_{W} \equiv v_{I} \cos (\Theta_{I} + 90^{\circ}), \quad v_{N} \equiv v_{I} \sin (\Theta_{I} + 90^{\circ}).$$

The position of a satellite on the sky can be described by the angles ($\rho, \Phi$), where $\rho$ is the angular distance from M31 and $\Phi$ is the position angle with respect to M31 measured from north over east (as defined in van der Marel & Cioni 2001; van der Marel et al. 2002). Because satellites are not located on the same position on the sky as M31, the vector $v_{\text{M31}}$ has a different decomposition in line-of-sight and transverse components than it does for M31. More specifically, the line-of-sight velocity of a satellite is

$$v_{\text{sat,los}} = v_{\text{los}} + v_{I} \sin \rho \cos (\Phi - \Theta_{I}) + v_{\text{pec,los}}.$$

The factor $\cos \rho$ in the first term indicates that only a fraction of $v_{\text{los}}$ is seen along the line of sight. The second term is an apparent solid body rotation component in the $v_{\text{sat,los}}$ velocity field on the sky, with amplitude $v_{I} \sin \rho$ and kinematic major axis along position angle $\Theta_{I}$. The last term merely adds a scatter $\sigma$ on top of the velocity field defined by the first two terms.

It follows from equation (3) that the transverse velocity of M31 affects the line-of-sight velocities of its satellites. Therefore, a study of the line-of-sight velocities of the satellites can constrain the M31 transverse velocity. To this end we compiled the sample in Table 1, which consists of M31 satellites with known velocities. The sample is based on that used by Evans et al. (2000), but with addition of the more recently discovered Andromeda dwarf satellites And IX and X. The satellites And XI and XIII (Martin et al. 2006, who also report the finding of an unusually distant globular cluster) and And XV and XVI (Ibata et al. 2007) are not included because no line-of-sight velocity measurements have yet been reported for them. We fitted equation (3) to these data by determining the values of $(v_{\text{los}}, v_{W}, v_{N})$ that minimize the scatter in $v_{\text{pec,los}}$. The resulting scatter is the dispersion $\sigma$ of the satellite population.

### Table 1

| Name           | Type       | $\rho$ (deg) | $\Phi$ (deg) | $v_{\text{los}}$ (km s$^{-1}$) |
|----------------|------------|--------------|--------------|---------------------------------|
| M31            | SB I–II    | 0.00         | ...          | -301 $\pm$ 1                    |
| M32            | E2         | 0.40         | -197.10      | -205 $\pm$ 3                    |
| NGC 205        | dSph       | 0.60         | -46.61       | -244 $\pm$ 3                    |
| And IX         | dSph       | 2.69         | 43.32        | -211 $\pm$ 3                    |
| And I          | dSph       | 3.27         | 169.84       | -380 $\pm$ 2                    |
| And XII        | dSph       | 4.97         | -163.13      | -355 $\pm$ 10                   |
| And X          | dSph       | 5.62         | 48.96        | -164 $\pm$ 3                    |
| NGC 185        | dSph/dE3   | 7.09         | -5.07        | -202 $\pm$ 7                    |
| NGC 147        | dSph/dE5   | 7.43         | -12.29       | -193 $\pm$ 3                    |
| And V          | dSph       | 8.03         | 35.31        | -403 $\pm$ 4                    |
| And II         | dSph       | 10.31        | 136.82       | -188 $\pm$ 3                    |
| M33            | Sc II–III  | 14.78        | 131.78       | -180 $\pm$ 1                    |
| And VII/Cas    | dSph       | 16.17        | -47.93       | -307 $\pm$ 2                    |
| IC 10          | dImr       | 18.37        | -9.11        | -344 $\pm$ 5                    |
| And VI/Peg     | dSph       | 19.76        | -143.64      | -354 $\pm$ 3                    |
| LGS 3/Pisces   | dImr/dSph  | 19.89        | 165.44       | -286 $\pm$ 4                    |
| Pegasus        | dImr/dSph  | 31.01        | -143.37      | -182 $\pm$ 2                    |
| IC 1613        | dImr       | 39.44        | 171.30       | -232 $\pm$ 5                    |

Notes.—The sample of M31 satellites used in the modeling of § 2.1. M31 itself is listed on the first line for comparison. Col. (1) lists the galaxy name and col. (2) its type.Cols. (3) and (4) define the position on the sky: $\rho$ is the angular distance from M31, and $\Phi$ is the position angle with respect to M31 measured from north over east. These angles were calculated from the sky positions (R.A., decl.) as in van der Marel et al. (2002). The satellites in the table are sorted by their value of $\rho$. Col. (5) lists the heliocentric line-of-sight velocity and its error. Velocities and sky positions (R.A., decl.) for most satellites were obtained from the compilation of Evans et al. (2000), except for the satellites And IX and X, which had not yet been discovered in 2000. For those we used the velocity measurements (R.A., decl.) given by Chapman et al. (2005) and J. S. Kalirai et al. (2008, in preparation), respectively.
motion studies of Local Group galaxies. Brunttaler et al. (2005, 2007) recently determined the proper motions for two galaxies in the M31 group, namely, M33 and IC 10. Unfortunately, no water masers have yet been found in M31, and, at present detection limits, maybe none should be expected (Brunttaler et al. 2006). So the direct application of this technique to M31 may not be possible in the foreseeable future. However, the measurements for M33 and IC 10 can be used to constrain the transverse velocity of M31 indirectly. Equation (1) implies that the unknown velocity vector of M31 can be estimated from the known velocity vector of a satellite as \( v_{M31} = v_{\text{sat}} - v_{\text{pec}} \). Since the peculiar velocity is unknown, it acts as a Gaussian uncertainty of size \( \sigma \) in each velocity component.

In analogy with equation (3), one can write for the transverse velocity components of the satellite

\[
\begin{align*}
{v}_{\text{sat},2} &= -v_{\text{sys}} \sin \rho + v_{T} \cos \rho \cos (\Phi - \Theta) + v_{\text{pec},2}, \\
{v}_{\text{sat},3} &= -v_{\text{sys}} \sin \rho + \frac{v_{T} \sin (\Phi - \Theta) + v_{\text{pec},3}}. \\
\end{align*}
\]

Here the unit vectors 2 and 3 on the plane of the sky are related to the directions of west and north, all at the position of the satellite, according to a rotation

\[
\begin{pmatrix}
{v}_{\text{sat},N} \\
{v}_{\text{sat},W}
\end{pmatrix}
= 
\begin{pmatrix}
\cos \Gamma & -\sin \Gamma \\
\sin \Gamma & \cos \Gamma
\end{pmatrix}
\begin{pmatrix}
{v}_{\text{sat},2} \\
{v}_{\text{sat},3}
\end{pmatrix}.
\]

where the rotation angle \( \Gamma \) is determined by

\[
\begin{align*}
\cos \Gamma &= \frac{\sin \delta \cos \delta_{0} (\alpha - \alpha_{0}) - \cos \delta \sin \delta_{0}}{\sin \rho}, \\
\sin \Gamma &= \frac{-\cos \delta_{0} \sin (\alpha - \alpha_{0})}{\sin \rho}. \\
\end{align*}
\]

Here \((\alpha, \delta)\) are the right ascension and declination of the satellite, and \((\alpha_{0}, \delta_{0})\) are the right ascension and declination of M31 (i.e., the position with \( \rho = 0 \)).

Given values of \((v_{\text{sat},\text{los}}, v_{\text{sat},W}, v_{\text{sat},N})\), the equations (2)–(6) uniquely constrain the three unknown components \((v_{\text{sys}}, v_{T}, v_{\nu})\) of the M31 velocity vector. We solve these equations for each of the two satellites M33 and IC 10. We take \( v_{\text{sat},\text{los}} \) from Table 1. To obtain \( v_{\text{sat},W} \) and \( v_{\text{sat},N} \) we write each velocity component as \( v = 0.0047404D_{\text{Hobs}} - \delta_{\text{frot}} \), where \( D_{\text{Hobs}} \) is the observed proper motion in \( \mu_{\alpha} \ yr^{-1} \), \( D \) is the satellite distance in kpc, and \( \delta_{\text{frot}} \) is a correction for the internal rotation of the galaxy under study. We take \( D = 794 \pm 23 \) kpc for M33 (McConnachie et al. 2004) and \( D = 660 \pm 65 \) kpc for IC 10 (Evans et al. 2000). The other quantities follow from Brunttaler et al. (2005, 2007):

\[
\begin{align*}
(\mu_{\alpha,\text{obs}}, \mu_{\delta,\text{obs}}) &= (-4.7 \pm 3.2, -14.1 \pm 6.4) \mu \text{as yr}^{-1} \text{for M33}; \\
(\mu_{\alpha,\text{obs}}, \mu_{\delta,\text{obs}}) &= (-6.0 \pm 5.0, 23.0 \pm 5.0) \mu \text{as yr}^{-1} \text{for IC 10}; \\
(\delta_{\text{frot}}) &= (70 \pm 23, -81 \pm 23) \text{ kpc for M33}; \\
(\delta_{\text{frot}}) &= (25 \pm 19, 9 \pm 19) \text{ kpc for IC 10}. \\
\end{align*}
\]

We do not include the Brunttaler et al. corrections for the reflex motion of the Sun, since we deal with that issue separately in §3.1. We add Gaussian random deviates in our calculations to reflect the uncertainties. We take each component of \( v_{\text{pec}} \) to be a Gaussian random deviate with dispersion \( \sigma = 76 \text{ km s}^{-1} \), as determined in §2.1. For each combination of \((v_{\text{sat},\text{los}}, v_{\text{sat},W}, v_{\text{sat},N})\) we solve the equations to obtain \((v_{\text{sys}}, v_{T}, v_{\nu})\) and we repeat this in Monte Carlo fashion. We adopt the average and dispersion of the results as our final estimate for the M31 velocity vector and its error. Using M33, we obtain the following estimates for M31:

\[
\begin{align*}
\text{sat} \: v_{\text{sys}} &= -183 \pm 76 \text{ km s}^{-1}, \quad v_{T} = -48 \pm 80 \text{ km s}^{-1}, \quad v_{\nu} = 71 \pm 84 \text{ km s}^{-1}. \\
\text{IC} 10 \: v_{\text{sys}} &= -346 \pm 76 \text{ km s}^{-1}, \quad v_{T} = -16 \pm 80 \text{ km s}^{-1}, \quad v_{\nu} = -47 \pm 81 \text{ km s}^{-1}. \\
\end{align*}
\]
2.3. Constraints from Line-of-Sight Velocities of Outer Local Group Galaxies

The Local Group contains not only the virialized subgroups of galaxies surrounding the Milky Way and M31, but also a number of unattached galaxies that populate the outer regions of the Local Group. On average, these galaxies are expected to follow the motion of the Local Group barycenter through space. Their heliocentric line-of-sight velocity vectors, averaged in a three-dimensional sense, therefore statistically equal the reflex motion of the Sun with respect to the Local Group barycenter. Since the velocity of the barycenter is itself determined by the relative velocity of M31 with respect to the Milky Way, this yields a determination of the latter. Variations of this method have been applied in the past by, e.g., Yahil et al. (1977), Lynden-Bell & Lin (1977), and Einasto & Lynden-Bell (1982). It is now worthwhile to revisit this method, since available information on the membership and distances of Local Group galaxies has evolved significantly in the past decades.

We adopt a Cartesian coordinate system \((X, Y, Z)\), with the origin at the Galactic center, the \(Z\)-axis pointing toward the Galactic north pole, the \(X\)-axis pointing in the direction from the Sun to the Galactic center, and the \(Y\)-axis pointing in the direction of the Sun’s Galactic rotation. For the set of outer Local Group galaxies \(j = 1, \ldots, N\) we calculate the unit vector \(r_i\) in the direction of each galaxy. If the velocity vector of the Sun with respect to the Local Group barycenter is \(U_\odot\), then one has

\[
\sum_j \left( v_{\text{los},j} + (U_\odot \cdot r_i) r_i \right) = 0,
\]

where \(v_{\text{los},j}\) is the heliocentric line-of-sight velocity for each galaxy. This can be written as a \(3 \times 3\) matrix equation for the components of the vector \(U_\odot\). The best-fit values and their formal errors are easily obtained using standard techniques (Einasto & Lynden-Bell 1982). Once this solution is obtained one can calculate the velocity of the Milky Way with respect to the Local Group barycenter, \(U_{\text{MW}} = U_\odot - V_\odot\). Here \(V_\odot\) is the velocity vector of the Sun in the galactocentric rest frame. For the circular velocity of the local standard of rest (LSR) we use the standard IAU value \(V_0 = 220\ \text{km s}^{-1}\) (Kerr & Lynden-Bell 1986), to which we assign an uncertainty \(10\ \text{km s}^{-1}\) (none of our results depend sensitively on this quantity). For the residual velocity of the Sun with respect to the LSR we adopt the values of Dehnen & Binney (1998). If we assume that all of the mass of the Local Group resides in the Milky Way and M31, then the barycenter is simply the mass-weighted average of their position vectors. This implies in the galactocentric rest frame that the velocity of M31 is

\[
V_{\text{M31}} = -U_{\text{MW}}/f_{\text{M31}}\ \text{where } f_{\text{M31}} = M_{\text{M31}}/(M_{\text{M31}} + M_{\text{MW}}).
\]

The heliocentric velocity of M31 is therefore \(v_{\text{M31}} = V_{\text{M31}} - V_\odot\). After substitution of the previous equations this yields

\[
v_{\text{M31}} = -U_\odot/f_{\text{M31}} + V_\odot[1/(f_{\text{M31}}) - 1].
\]

This heliocentric vector can be decomposed into components along the line of sight and in the west and north directions following the methodology of van der Marel et al. (2002).

Application of equation (8) requires that we assume a value for \(f_{\text{M31}}\). Einasto & Lynden-Bell (1982) used the Tully-Fisher relation to constrain this quantity and built this constraint directly into their matrix solution for \(u_\odot\). However, the mass ratio of M31 and the Milky Way is not actually all that well known observationally, and different arguments for estimating it have yielded different results. Our aim here is to constrain \(v_{\text{M31}}\) from observational data, while imprinting a minimum amount of theoretical prejudice into the result. So we simply assume that \(f_{\text{M31}}\) is homogeneously distributed between 0.39 and 0.67 (i.e., \(M_{\text{M31}}/M_{\text{MW}} = 0.8 \pm 0.2\)). This encompasses most of the values that have been quoted in the literature (see discussion in § 4.2). We then solve equation (8) in Monte Carlo fashion, while simultaneously adding the random errors in \(U_\odot\) and \(V_\odot\). This yields the best-fit result for \(v_{\text{M31}}\) and its statistical uncertainties.

We base our analysis on the sample of Local Group dwarf galaxies (there are no giant galaxies in the outer parts of the Local Group) compiled by Grebel et al. (2003). From their Table 1 we removed all galaxies listed as being (potentially) part of the Milky Way or M31 subgroups. We obtained the heliocentric line-of-sight velocities of the galaxies from the NASA Extragalactic Database (NED). We removed the Cetus dwarf from the sample, since it has no line-of-sight velocity available. We restricted our primary sample to galaxies with a Local Group barycentric distance less than \(\sim 1.2\ \text{Mpc}\). The resulting sample consists of five galaxies, which are listed in Table 2. With this sample the analysis yields for M31: \(v_{\text{sys}} = -405 \pm 114\ \text{km s}^{-1}\), \(v_{\text{off}} = -126 \pm 63\ \text{km s}^{-1}\), and \(v_N = -89 \pm 50\ \text{km s}^{-1}\) (see also Table 3 below). The fit yields an estimate \(\sigma = 22\ \text{km s}^{-1}\) for the one-dimensional dispersion of the galaxies around the space motion of the Local Group barycenter. The small value of this dispersion is due to the fact that the sample galaxies reside at an average Local Group barycentric distance of 0.98 Mpc, which is consistent with the Local Group turnaround radius (e.g., Karachentsev et al. 2002), where the velocity with respect to the Local Group barycenter is zero by definition.

| Name                 | Type | R.A. | Decl. | \(v_{\text{los}}\) | \(D\) | \(D_{\text{hary}}\) |
|----------------------|------|------|-------|-------------------|------|-----------------|
| WLM                  | dIrr | 0.49234 | -15.46093 | -122 ± 2 | 945 ± 40 | 802 |

Notes.—The sample of outer Local Group galaxies used in the modeling of § 2.3. Col. (1) lists the galaxy name and col. (2) its type. Cols. (3) and (4) give the position on the sky. Col. (5) lists the heliocentric line-of-sight velocity and, where available, its error. Velocities and sky positions (R.A., decl.) were obtained from the NASA Extragalactic Database (NED). Col. (6) lists the heliocentric distance and its error from Grebel et al. (2003). Col. (7) lists the Local Group barycentric distance \(D_{\text{hary}}\), calculated assuming the M31 distance listed in § 3.1 and a mass fraction \(f_{\text{M31}} = 0.53\). The galaxies in the table are sorted by their value of \(D_{\text{hary}}\).
TABLE 3
M31 HELIOCENTRIC VELOCITY ESTIMATES

| Method               | \(v_{\text{sys}}\) (km s\(^{-1}\)) | \(v_W\) (km s\(^{-1}\)) | \(v_N\) (km s\(^{-1}\)) |
|----------------------|-------------------------------------|---------------------------|--------------------------|
| M31 satellites       | -270 ± 19                          | -136 ± 148               | -5 ± 75                  |
| M33 PM                | -183 ± 76                          | -48 ± 80                 | 71 ± 84                  |
| IC 10 PM             | -346 ± 76                          | -16 ± 80                 | -47 ± 81                 |
| Outer LG galaxies    | -405 ± 114                         | -126 ± 63                | -89 ± 50                 |
| Weighted average     | -273 ± 18                          | -78 ± 41                 | -38 ± 34                 |

Notes.—Estimates of the heliocentric velocity of M31 estimated using different methods, as indicated in col. (1). The method based on the M31 satellite ensemble line-of-sight velocities is described in § 2.1, and that based on the observed proper motions (PMs) of M33 and IC 10 is described in § 2.2, and that based on the line-of-sight velocities of the satellites in outer regions of the Local Group is described in § 2.3. Col. (2) lists the estimated M31 systemic line-of-sight velocities. Cols. (3) and (4) lists the estimated M31 transverse velocities in the west and north directions, respectively. The bottom row of the table lists the weighted average of the results from the different methods.

The table shows that the weighted average of the transverse velocities in the west and north directions are -78 ± 41 km s\(^{-1}\) and -38 ± 34 km s\(^{-1}\), respectively.

In the comparison of the analyses in § 2.1 and the present section, there is an important difference in the expected galaxy velocities. The velocities of satellites around M31 are virialized, so the expectation value of a satellite velocity with respect to M31 is zero, independent of where the satellite is located on the sky. By contrast, the motions of the outer Local Group galaxies around the Local Group barycenter are not virialized. Therefore, the expectation value of a galaxy velocity with respect to the Local Group barycenter is zero only if the galaxy is near the turnaround radius. If this is not the case, then equation (7) is valid only if the galaxies are distributed homogeneously around the Local Group. In reality, both the distribution is nonhomogeneous and the number of galaxies is small. Therefore, addition to the sample of galaxies beyond the turnaround radius is expected to add both bias and shot noise to the estimate of the M31 velocity. Moreover, galaxies significantly outside the turnaround radius do not necessarily need to follow the Local Group barycenter motion.

The sample in Table 2 consists of a rather small number of galaxies. So despite the aforementioned disadvantages, we did study the effect of adding more Local Group galaxies at larger barycentric distances. In particular, we tried to add the only other six Local Group galaxies within 2 Mpc (namely: NGC 3109, Antlia, Sextans A and B, IC 5152, and KKR 25; Grebel et al. 2003) that are not believed to be associated with any other nearby structures. These reside at barycentric distances of 1.6–1.9 Mpc. Analysis of the combined sample of 11 galaxies yields for M31: \(v_{\text{sys}} = -608 ± 154\) km s\(^{-1}\), \(v_W = -82 ± 138\) km s\(^{-1}\), \(v_N = -46 ± 82\) km s\(^{-1}\). The fit yields an estimate \(\sigma = 50\) km s\(^{-1}\) for the one-dimensional dispersion of the galaxies along the space motion of the Local Group barycenter. The large deviation of \(v_{\text{sys}}\) from the observed value, as well as the increased \(\sigma\) and formal errors supports our assertion that adding these distant galaxies decreases the quality of the results. Nonetheless, the results for \(v_W\) and \(v_N\) are consistent with those inferred from the smaller sample, within the errors. So we conclude that the results for the M31 transverse motion are quite robust and not very sensitive to the composition of the sample. This is further supported by the fact that our results are consistent within the errors with the preferred solutions obtained by Einasto & Lynden-Bell (1982), despite their use of a sample that is only partially overlapping with ours.

2.4. Comparison and Combination of Constraints

The \(v_W\) and \(v_N\) for M31 inferred from the different methods and listed in Table 3 are shown in Figure 2 as colored data points with error bars. The weighted averages of all four of the independent estimates are \(\langle v_W \rangle = -78 ± 41\) km s\(^{-1}\) and \(\langle v_N \rangle = -38 ± 34\) km s\(^{-1}\). This is shown in the figure as a black data point with error bars.

The \(\chi^2\) that measures the residuals between the individual measurements in Table 3 and the weighted averages is \(\chi^2 = 8.1\) for \(N = 9\) degrees of freedom (12 measurements minus 3 parameters). Therefore, the results for the \(v_W\) and \(v_N\) from the different methods are consistent within the errors. Among other things, this implies that there is no evidence that the dispersion of the peculiar velocities of M31 satellites in the transverse direction, which enters into the analysis of § 2.2, is larger than the value \(\sigma = 76\) km s\(^{-1}\) derived from line-of-sight velocities in § 2.1. This is consistent with the assumption that was made about the isotropy of the peculiar velocities.

The inferred weighted average of the three independent systemic velocity estimates is \(\langle v_{\text{sys}} \rangle = -273 ± 18\) km s\(^{-1}\). This differs at the 1.6 \(\sigma\) level from the observed M31 velocity \(v_{\text{sys}} = -301 ± 1\) km s\(^{-1}\) (Courteau & van den Bergh 1999), but the agreement in an absolute sense is better than the formal uncertainties in \(\langle v_W \rangle, \langle v_N \rangle\). So this comparison provides no reason to mistrust our assumptions that the M31 satellites (§§ 2.1 and 2.2) and the outer Local Group galaxies (§ 2.3) move on average through space with the same velocity as M31 and the Local Group barycenter, respectively (see Lynden-Bell 1999 for an earlier discussion of this).

The analyses in the previous sections make assumptions about the velocity distributions of the satellites, but not about their spatial distributions. These spatial distributions are known to be

Fig. 2.—Estimates of the M31 heliocentric transverse velocity in the west and north directions. Data points with error bars are from Table 3 based on the M31 satellite ensemble line-of-sight velocities (blue), the proper motion of M33 (green), the proper motion of IC 10 (red), the line-of-sight velocities of outer Local Group satellites (magenta), or the weighted average of these results (black). The starred symbol indicates the transverse velocity that corresponds to a radial orbit for M31 on the Milky Way. The cyan rectangle approximates the region that is ruled out in all of the theoretical models explored by Loeb et al. (2005), because the resulting orbit of M31 and M33 would have produced more disruption of the M33 disk than is observed. The small dots are the 18% of 30,000 samplings from the error ellipse belonging to the black data point that are consistent with the theoretical constraint.
inhomogeneous. In the case of the M31 subgroup, there are more satellites on the near side of M31 (i.e., between M31 and the Milky Way) than on the far side (e.g., McConnachie & Irwin 2006). Moreover, recent studies have suggested that (some of the) satellites are concentrated near a plane surrounding M31 (e.g., Koch & Grebel 2006). These facts by themselves do not affect our analysis at all, as long as the velocity distributions remain isotropic. However, the analysis would be affected if the satellite ensemble possesses a mean rotation. This is possible in some of the scenarios that have been suggested for a possible disklike distribution of satellites (but not necessarily the favored scenarios; see, e.g., Metz et al. 2007). In the method of § 2.1 we fit an apparent solid-body rotation field (eq. [3]) to the observed satellite velocities. Any intrinsic rotation would therefore bias the inferred transverse velocity. However, if this had been the case, then we might have expected the M31 transverse velocity results of this method to be inconsistent with the results from the other methods that we have used, and in particular the method of § 2.3 based on outer Local Group galaxies. The fact that the results from the different methods are actually statistically consistent therefore suggests that our results are not affected by potential rotation of the M31 satellite system.

In the comparisons of the different estimates listed in Table 3 it should be noted that they are not completely independent, because the line-of-sight velocities of M33 and IC 10 enter not only in the analysis of § 2.2, but also in that of § 2.1. However, this is not a very important issue. We verified that if M33 and IC 10 are removed from the line-of-sight velocity analysis in § 2.1, then the changes in the results are well within the uncertainties.

3. ORBITS

3.1. M31–Milky Way Orbit

To calculate the velocity of M31 in the galactocentric rest frame we adopt the same Cartesian coordinate system (X, Y, Z) as in § 2.3. We adopt a distance $D = 770 \pm 40$ kpc for M31 (Holland 1998; Joshi et al. 2003; Walker 2003; Brown et al. 2004; McConnachie et al. 2005; Ribas et al. 2005). The position of M31 is then $r = (-379.2, 612.7, -283.1)$ kpc. To calculate the reflex motion of the Sun at the position of M31 we use the same solar velocity as in § 2.3 and we use the standard IAU value $R_0 = 8.5$ kpc for the distance of the Sun from the Galactic center (Kerr & Lynden-Bell 1986), to which we assign an uncertainty of 0.5 kpc (none of our results depend sensitively on this quantity). The velocity of the Sun then projects to $(v_{\text{sys}}, v_{\odot}) = (172, 128, 71)$ km s$^{-1}$ at the position of M31. Since one observes the reflex of this, these values must be added to the observed M31 velocities to obtain its velocity in the galactocentric rest frame. The velocity vector corresponding to the observed velocity component $v_{\text{sys}}$ given in Table 1 and the inferred $(v_{\odot}, v_{\odot})$ given in Table 3 is then $v_{\text{obs}} = (97 \pm 35, -67 \pm 26, 80 \pm 32)$ km s$^{-1}$. The errors (which are correlated between the different components) were obtained by propagation of the errors in the individual position and velocity quantities (including those for the Sun) using a Monte Carlo scheme.

If the transverse velocity of M31 in the galactocentric rest frame, $v_{\text{tan}}$, equals zero, then M31 moves straight toward the Milky Way on a purely radial (head-on collision) orbit. This orbit has $(v_{\odot}, v_{\odot})_{\text{rad}} = (-127, -71)$ km s$^{-1}$ (this is approximately the reflex of the velocity of the Sun quoted above, because the lines from the Sun to M31 and from the Galactic center to M31 are almost parallel). The radial orbit is indicated as a starred symbol in Figure 2. The velocity $v_{\text{obs}}$ calculated in the previous paragraph has tangential and radial components $v_{\text{tan,obs}} = 59$ km s$^{-1}$ and $v_{\text{rad,obs}} = -130$ km s$^{-1}$. The total velocity is $|v_{\text{obs}}| = 142$ km s$^{-1}$.

The value $V_{\text{rad,obs}}$ is an unbiased estimator of the true radial velocity $V_{\text{rad}}$. The associated uncertainty can be calculated in a straightforward fashion using the previously described Monte Carlo scheme. This yields $V_{\text{rad}} = -130 \pm 8$ km $s^{-1}$. The uncertainty is due mostly to the uncertainty in our knowledge of the circular velocity of the LSR in the Galactic plane. The values of $V_{\text{tan,obs}}$ and $|V_{\text{obs}}|$ are more difficult to interpret because they are not unbiased estimators of the true velocities $V_{\text{tan}}$ and $|V|$. This is because the area coverage of $V_{\text{tan}}$ values in the $(v_{\odot}, v_{\odot})$ plane scales as $2\pi V_{\text{tan}} dV_{\text{tan}}$, which produces a bias in the sense that any measurement error in $(v_{\odot}, v_{\odot})$ tends to yield overestimates of $V_{\text{tan}}$ and $|V|$. To quantify and correct these biases we used Bayes’ theorem, which yields the identity

$$P(V_{\text{tan}}|V_{\text{tan,obs}}) \propto P(V_{\text{tan}})P(V_{\text{tan,obs}}|V_{\text{tan}}).$$

We are interested in the quantity on the left-hand side, which is the probability distribution of $V_{\text{tan}}$, given our measurement. The quantity $P(V_{\text{tan}})$ on the right-hand side is the Bayesian prior probability of $V_{\text{tan}}$, which we assume to be flat (i.e., homogeneous). The quantity $P(V_{\text{tan,obs}}|V_{\text{tan}})$ is the probability of measuring a value $V_{\text{tan,obs}}$ if the actual value is $V_{\text{tan}}$. This latter distribution is easily calculated using Monte Carlo drawings because the measurement uncertainties are known. Once the distributions $P(V_{\text{tan,obs}}|V_{\text{tan}})$ have been precalculated for all $V_{\text{tan}}$, it is straightforward to obtain a Monte Carlo sampling of the probability distribution $P(V_{\text{tan}}|V_{\text{tan,obs}})$. To this end one draws a random deviate $V_{\text{tan}}$ and then accepts this value with probability $P(V_{\text{tan,obs}}|V_{\text{tan}})$. The top left panel of Figure 3 shows the probability distribution $P(V_{\text{tan}}|V_{\text{tan,obs}})$ thus obtained. The median $V_{\text{tan}} = 42$ km s$^{-1}$. The fact that this is smaller than $V_{\text{tan,obs}} = 59$ km s$^{-1}$ quantifies the aforementioned bias. The 1 σ confidence interval is $V_{\text{tan}} \leq 56$ km s$^{-1}$. So the radial orbit is consistent with the data at this confidence level. These results are discussed in the context of previous model predictions in § 4.1. When combined with the value for $V_{\text{rad}}$, the 1 σ confidence interval around the median for the total velocity is $|V| = 138^{+14}_{-15}$ km s$^{-1}$.

To get insight into the relative orbit of M31 and the Milky Way we assume that they can be approximated as point masses of mass $M_{M31}$ and $M_{MW}$, respectively. In the center-of-mass frame, their orbit then has energy $E = \frac{1}{2} |r|^2 - G M_{M31} M_{MW} / |r|$ and angular momentum $L = |r| \times |V|$, where the total mass is $M = M_{M31} + M_{MW}$ and the reduced mass is $\mu = M_{M31} M_{MW} / M$. The galaxies are bound to each other (E < 0) if $M \geq M_{\text{bound, min}} = |r| |V|^2 / 2G$. The orbit of the separation vector $r$ is then a Kepler ellipse with eccentricity $e^2 = 1 + (2E^2 / G^2 M^2 \mu^3)$ and semimajor axis length $a = L^2 / (G M \mu^2 (1 - e^2))$. The pericenter separation is $r_{\text{per}} = a(1 - e)$. The period is $T = 2\pi (a^3 / GM)^{1/2}$. The orbit can be parameterized using the eccentric anomaly $\eta$ as (e.g., Kibble 1985; Binney & Tremaine 1987)

$$r = a(1 - e \cos \eta),$$

$$t = (a^3 / GM)^{1/2} (\eta - e \sin \eta).$$

In this parameterization $\eta = 0$ corresponds to the pericenter passage at $t = 0$, while $\eta = 2\pi$ corresponds to the next pericenter passage at $t = T$. The radial and tangential velocities can be similarly parameterized as (e.g., Kochanek 1996)

$$V_{\text{rad}} = (GM / a)^{1/2} (e \sin \eta) / (1 - e \cos \eta),$$

$$V_{\text{tan}} = (GM / a)^{1/2} (1 - e^2)^{1/2} / (1 - e \cos \eta).$$

(11)
It is generally assumed that the Local Group is a bound system that, due to its overdensity, decoupled from the Hubble expansion at fairly high redshift. Since then the orbital evolution of M31 and the Milky Way has been governed by Newtonian dynamics. Given this scenario and the orbital description given by equation (10), the big bang must have corresponded to a previous pericenter passage, which we can take to be $t = 0$. The current time $t$ then corresponds to the age of the universe, which has been tightly constrained using data from the Wilkinson Microwave Anisotropy Probe to be $t = 13.73_{-0.15}^{+0.16}$ Gyr (Spergel et al. 2007). With measurements of the current galactocentric distance $r$ and velocities $V_{\text{rad}}$ and $V_{\text{tan}}$, the equations (10) and (11) can be solved for the quantities $M$, $a$, $e$, and $\eta$. The quantity $\eta$ must be in the interval $[\pi, 2\pi]$ (so that M31 and the Milky Way are falling toward each other for the first time), since implausibly high masses $M$ are otherwise required.

This methodology for modeling the Local Group is commonly called the “timing argument.” It has been widely applied and discussed in the literature (e.g., Kahn & Woltjer 1959; Lynden-Bell 1981, 1999; Einasto & Lynden-Bell 1982; Raychaudhury & Lynden-Bell 1989; Kroeker & Carlberg 1991; Kochanek 1996; Loeb et al. 2005), mostly to obtain joint estimates for the age of the universe and the mass of the Local Group, often assuming a purely radial orbit. We can now do a more accurate analysis, both because we have an observational estimate of $V_{\text{tan}}$ and because the age of the universe can be assumed to be well known from independent data. We have used this methodology on our results. Monte Carlo error propagation was performed as described above to obtain full probability distributions of $M$, $a$, $e$, $\eta$, $T$, and $r_{\text{peri}}$. The results are shown as histograms in Figure 3. The inferred 1 $\sigma$ confidence intervals around the median are $M = 5.58_{-0.72}^{+0.85} \times 10^{12} M_\odot$; $a = 561_{-26}^{+29}$ kpc; $\eta = 4.301_{-0.047}^{+0.047}$ rad; $r_{\text{peri}} = 23$ kpc, with 1 $\sigma$ confidence interval $r_{\text{peri}} \leq 40.9$ kpc; $T = 16.70_{-0.27}^{+0.27}$ Gyr; and $e = 0.959$, with 1 $\sigma$ confidence interval $(1 - e) \leq 0.072$. The implications of this result for $M$ are discussed in § 4.2. The uncertainties in the listed quantities are due primarily to the uncertainties in $V_{\text{tan}}$ and the M31 distance $D$. The uncertainties in these quantities contribute more or less equally to the uncertainties in $M$, $a$, $\eta$, and $T$. The uncertain-
$T$ and $\eta$. The uncertainties in the distance have little effect on $e$ and $r_{\text{peri}}$. All quantities vary monotonically with $V_{\text{tan}}$ and $D$. Larger values of $V_{\text{tan}}$ yield larger values of $M$, $a$, $\eta$, $T$, and $r_{\text{peri}}$, and smaller values of $e$. Larger values of $D$ yield larger values of $M$, $a$, $e$, $T$, and $r_{\text{peri}}$, and smaller values of $\eta$. Figure 3 also shows the probability distribution of $M_{\text{bind, min}}$, the minimum mass required for a bound orbit. The inferred $1\sigma$ confidence interval around its median is $M_{\text{bind, min}} = 1.72^{+0.26}_{-0.25} \times 10^{12} M_\odot$.

The anticipated collision between M31 and the Milky Way will happen at the next orbital pericenter, which in the Kepler model is at $T - t \approx 3.0 \pm 0.3$ Gyr from now. The orbital pericenter distance is much smaller than the sizes of the galaxies’ dark halos. If the galaxies are assumed to have a logarithmic density profile and a flat rotation curve, then their radial extents $r$ and $v$ are $235(M_{\text{M31}}/3.4 \times 10^{12} M_\odot)$ kpc and $207(M_{\text{M31}}/2.3 \times 10^{12} M_\odot)$ kpc, respectively (Loeb et al. 2005). The dark halos will intersect once the orbital separation becomes smaller than the sum of these sizes. This will have two consequences. First, the orbits will deviate from Kepler ellipses in the sense that the orbit will have less curvature and larger $r_{\text{peri}}$ than indicated by the previously derived Kepler orbit. Second, there will be dynamical friction, which will tend to increase the curvature and will tend to decrease $r_{\text{peri}}$. More complicated calculations are necessary to properly calculate the orbit once the dark halos of the galaxies start to overlap and to study the properties of the resulting merger. Such calculations were recently presented by Cox & Loeb (2008). However, they adopted an orbit with $V_{\text{tan}} = 132$ km s$^{-1}$, $r_{\text{peri}} = 450$ kpc, and $e = 0.494$. Comparison to the top panel of Figure 3 shows that this orbit is not consistent with our measurement of the M31 transverse velocity.

### 3.2. M31-M33 Orbit

Loeb et al. (L05) recently derived a theoretical constraint on the transverse motion of M31 from the fact that M33 is relatively undisturbed. This appears to rule out orbits where M33 had a previous close interaction with M31. The exact shape of the region in $(r_{\text{peri}}, v)$ space thus ruled out (being defined by L05 as: more than 20% of the M33 stars would have been stripped) has a complex shape and depends somewhat on the modeling assumptions, but it can be approximated by the solid cyan rectangle in Figure 2. This is an approximation to Figure 2c of L05 (which quantified the transverse motion using galactocentric rest-frame velocities $V_{\text{accn}} = -v_y - 128$ km s$^{-1}$ and $V_z = v_y + 71$ km s$^{-1}$). In some of their models (see their Figs. 2a and 2b) even a somewhat larger region is ruled out.

The overall shape of the excluded region in $(r_{\text{peri}}, v)$ space can be understood with fairly simple calculations and arguments. In doing so, we ignore the observational uncertainties in the quantities of interest. This is sufficient for the scope of the present discussion, but they should be included for more quantitative understanding of the M31-M33 orbit. Based on the data from Table 1 and the M33 and M31 distances from $\S$2.2 and 3.1, respectively, the distance between M33 and M31 is 203 kpc. The center of the excluded region in Figure 2 is at $(r_{\text{peri}}, v_y) \approx (-68, -11)$ km s$^{-1}$. This defines the three-dimensional velocity vector of M31, while for M33 that vector is known from Brünthaler et al. (2005). The radial and tangential velocity components of the separation vector are then $V_{\text{rad}} = -71$ km s$^{-1}$ and $V_{\text{tan}} = 126$ km s$^{-1}$. The Kepler orbit of the separation vector can be calculated similarly as in $\S$3.1. In doing so, we assume that $M_{\text{M31}} = 3.0 \times 10^{12}$, which is based on $M = 5.58 \times 10^{12} M_\odot$ ($\S$3.1) and $f_{\text{M31}} = 0.54$ (compare $\S$2.3). We assume that the M33-to-M31 mass ratio is equal to the value $\sim 118(250)^{0.5}$ suggested by the Tully-Fisher relation and the galaxies’ circular velocities (Corbelli & Schneider 1997; Klypin et al. 2002). The orbit then has $a = 120$ kpc, $r_{\text{peri}} = 27$ kpc, $T = 2.2$ Gyr, and $e = 0.77$. The value of $a$ is close to the minimum that this quantity can attain (i.e., maximum binding energy) as a function of $(v_y, v_y)$, which is $a_{\text{min}} = 113$ kpc. Given the value of $a$, M33 moves inside of the M31 dark halo for most of its orbit. Our assumption that all of the M31 mass resides at its center therefore overestimates the curvature of the orbit. The listed pericenter distance should thus be interpreted as a lower bound on the actual value. More detailed calculations, as in L05, are required to get a proper estimate of this quantity.

As one moves from $(v_y, v_y) \approx (-68, -11)$ km s$^{-1}$ along the diagonal that runs from the bottom left to the top right in Figure 2, the Kepler orbit value of $r_{\text{peri}}$ does not change much. However, $a$ increases, which means that the orbits become more eccentric and less bound (and ultimately unbound). The galaxies therefore spend less time in the close vicinity of each other, and the relative velocity at pericenter increases. By contrast, as one moves from $(v_y, v_y) \approx (-68, -11)$ km s$^{-1}$ along the diagonal that runs from the top left to the bottom right in Figure 2, the Kepler orbit value of $e$ does not change much. But again, $a$ increases, which means that the orbits have larger pericenter separations and become less bound (and ultimately unbound). The energy dissipated during an encounter scales as $dE \propto 1/(r^4V^2)$ in the impulsive tidal approximation (e.g., Binney & Tremaine 1987, their eq. [7-55]), where $r$ is the impact parameter. Therefore, as one moves away along either diagonal in Figure 2, the structure of M33 will be less perturbed by the encounter. The excluded region in Figure 2 can therefore be understood to lowest order as the region where the orbital integral over $dE$ exceeds some threshold, with $r$ and $V$ calculated on the basis of the Kepler orbit.

Interestingly, the observationally implied transverse velocity of M31 from Table 3 falls right in the region for which considerable tidal deformation of M33 would have been expected. This M31 velocity yields a Kepler orbit for the M31-M33 separation vector with $a = 127$ kpc, $r_{\text{peri}} = 30$ kpc, $T = 2.4$ Gyr, and $e = 0.76$. However, the uncertainties in the observationally implied velocities cannot be ignored. Upon performing Monte Carlo sampling we find that as much as 18% of samplings from the error ellipse fall outside the cyan rectangle in Figure 2 and therefore do not violate the M33 tidal stripping argument. These 18% are shown as small black dots for a total sample of 30,000 drawings. The black dots can be viewed as a visual representation of the probability distribution of M31’s transverse velocity obtained by taking into account not only the observational constraints derived here but also the theoretical M33 stripping argument of L05. Since most of the dots fall close to the cyan rectangle, it is likely that there has been some tidal deformation of M33 by M31 (although not sufficient to pass L05’s threshold for being considered excluded). This suggests that it will be worthwhile to perform deep searches for tidal tails and structures in the outer regions of M33, similar to those that have already been performed for M31 (e.g., Ferguson et al. 2002).

Our results for the relative M31-M33 orbit involve a small amount of circular reasoning, since we have assumed a priori that the residual space motion of M33 with respect M31 has the same dispersion ($\sigma = 76$ km s$^{-1}$ per coordinate, as derived from line-of-sight velocities in $\S$2.1) as do the other M31 satellites. To avoid this circular reasoning one could ignore the result labeled “M33 PM” in Table 3 (Fig. 2, green cross). The weighted average of the remaining M31 transverse motion estimates then becomes $(v_y) = -89 \pm 47$ km s$^{-1}$ and $(v_y) = -60 \pm 37$ km s$^{-1}$. This differs by only 24 km s$^{-1}$ from what we have used so far (last row of Table 3), and this difference is well within the uncertainties.
This modified result still falls well inside the region excluded by L05. Therefore, our conclusions about the M31-M33 orbit are not influenced by the fact that we have used the M33 space velocity as one of the estimators of the M31 space velocity.

L05 only considered models with $M_{\text{M31}} = 2.6 - 3.4 \times 10^{12} M_{\odot}$. As is discussed in § 4.2 below, it is possible that the M31 mass is actually lower than this. For example, Klypin et al. (2002) advocate $M_{\text{M31}} = 1.6 \times 10^{12} M_{\odot}$. It follows both from the simple arguments of § 3.2 and from the detailed calculations of L05 (their Fig. 2) that the amount of past tidal deformation of M33 is smaller for smaller values of $M_{\text{M31}}$. This would reduce the area of the excluded rectangular region in Figure 2 and would reduce the concern that our observational estimate of the M31 transverse velocity falls in the region of parameter space that was disfavored by L05. Also, the models of L05 (and hence the cyan region in Fig. 2) do not account explicitly for the observational uncertainties in the assumed distances of M31 and M33. If the actual distances differ at the 1 $\sigma$ or 2 $\sigma$ level from the canonical values, then this could affect the location of the excluded region in transverse-velocity space.

It is straightforward to include the theoretical constraint of L05 into the M31–Milky Way timing argument calculations of § 3.1. To address this, we applied the same Monte Carlo scheme as in that section, but now with rejection of all Monte Carlo drawn velocities with $(v_{\text{vir}}, v_{\text{v}})$ combinations in the region excluded by L05. This yields the probability histograms shown in red in Figure 3. The distributions of $v_{\text{tan}}$, $\epsilon$, and $v_{\text{peri}}$ become rather non-Gaussian, as can be easily understood from the distribution of points in Figure 2. However, the other distributions remain close to Gaussian and are not very different from those obtained without using the L05 M33 stripping argument. The same is true for the inferred 1 $\sigma$ confidence intervals around the median values. For example, for the Local Group mass we obtain $M = 5.50^{+1.14}_{-0.76} \times 10^{12} M_{\odot}$, which is similar to the result of § 3.1.

4. DISCUSSION

4.1. M31 Tangential Velocity

Many previous studies of the M31–Milky Way system have assumed that their orbit can be approximated to be radial ($v_{\text{tan}} \approx 0$). This simplifies analyses based on the timing argument and, in the absence of a reliable $v_{\text{tan}}$ measurement, was a reasonable guess based on simple cosmological arguments. In the absence of mutual gravitational interactions, peculiar velocities with respect to the Hubble flow decrease with time as $(1 + z)$. In the M31–Milky Way system there is mutual gravitational attraction along the galaxy separation vector. This changes the radial velocity $V_{\text{rad}}$ from positive (receding) at high $z$ to negative (approaching) at the present time, as quantified by the timing argument. However, the angular momentum is conserved in a two-body system without external perturbations. Therefore, a significant present-day tangential motion in such a system implies an unrealistically high peculiar velocity at high redshift.

The situation is more complicated when the possibility of angular momentum exchange is taken into account. Tidal torques can lead to exchange between the spin angular momentum of the galaxies and their orbital angular momentum. This process may have contributed both to the observed spins of M31 and the Milky Way and to the tangential velocity component in their orbital motion (Gott & Thuan 1978; Dunn & Laflamme 1993). More importantly, tidal torques exerted by the galaxies outside of the Local Group also induce a tangential velocity component in the M31–Milky Way system (Raychaudhury & Lynden-Bell 1989). A useful approach to study this effect and, more generally, the orbits of all the galaxies in the nearby universe is based on the principle of least action (Peebles 1989). This assumes that nearby galaxies arrived at their present configuration through gravitational interactions from a nearly homogeneous high-redshift state with negligible peculiar velocities. Allowed solutions are those that minimize the relevant Hamiltonian action integral. This method can be used to fit observed galaxy velocities starting from their observed positions (Peebles et al. 1989; Peebles1994), to fit observed galaxy distances starting from their observed velocities (Shaya et al. 1995; Schmoldt & Saha 1998), or to fit observed galaxy velocities and distances simultaneously (Peebles et al. 2001, hereafter P01; Pasetto & Chiosi 2007). The general prediction from the theoretical work that includes tidal torques is that M31 tangential velocities of $v_{\text{tan}} \leq 200$ km s$^{-1}$ are expected in plausible models.\footnote{The mass $M = M_{\text{M31}} + M_{\text{MW}}$ calculated with the timing argument is a monotonically increasing function of $v_{\text{tan}}$. So if one presumes an upper limit to $M$, then one also obtains an upper limit to $v_{\text{tan}}$. L05 used this approach to obtain $v_{\text{tan}} \leq 120$ km s$^{-1}$ based on the assumption that $M \leq 5.6 \times 10^{12} M_{\odot}$. However, no physical motivation was provided for this assumed mass limit. Larger values of $v_{\text{tan}}$ are not inconsistent with the timing argument, but they do require higher masses.}

Figure 6 of P01 shows the M31 transverse velocity vectors predicted in 30 minimum-action solutions for the nearby universe. The reason that there are multiple possible solutions is due to the absence of observational knowledge of most galaxy proper motions. P01 characterized the M31 velocity using supergalactic angular coordinates in the galactocentric rest frame. These are related to the heliocentric transverse velocity $v_{\text{t}}$ and the position angle $\Theta$ of the transverse motion on the sky, defined as in equation (2), according to

$$v_{\text{SGL}} = -v_{\text{t}} \cos(\Theta_{\text{t}} + 34.60^\circ) - 131 \text{ km s}^{-1},$$

$$v_{\text{SGB}} = v_{\text{t}} \sin(\Theta_{\text{t}} + 34.60^\circ) - 64 \text{ km s}^{-1}. \quad (12)$$

Our weighted average velocity $(v_{\text{SGL}}, v_{\text{SGB}})$ given in Table 3 corresponds to $(v_{\text{SGL}}, v_{\text{SGB}}) = (-55, -21)$ km s$^{-1}$. The 68.3$\%$ confidence ellipse around this measurement encloses eight of the 30 viable solutions presented by P01. Our measurement is therefore fully consistent with their theoretical work. The action method is based on the assumptions that mass follows light and that the galaxy peculiar velocities are due to their mutual gravitational interactions. Our M31 transverse motion determination therefore provides no reason to doubt these assumptions (although cosmological $N$-body simulations suggest that these assumptions are at best only approximately satisfied; Martinez-Vaquero et al. 2007). The mass $M_{\text{M31}} + M_{\text{MW}}$ assumed in the P01 models is $5.16 \times 10^{12} M_{\odot}$, which is consistent with the range calculated in Figure 3 based on the timing argument. The mass was not varied independently in P01 but is within the factor $\sim 2$ range of masses for which the action method yields plausible solutions (Peebles 1994). Pasetto & Chiosi (2007) obtained a best-fit solution from their action modeling that corresponds to a heliocentric velocity $(v_{\text{vir}}, v_{\text{v}}) = (-142, -41)$ km s$^{-1}$. This value is near the edge of our 68.3$\%$ confidence ellipse and is therefore also consistent with our measurement. The mass $M_{\text{M31}} + M_{\text{MW}}$ assumed in their models is $5.36 \times 10^{12} M_{\odot}$, which is also within the range calculated in Figure 3 based on the timing argument.

In summary, our measurement of the transverse velocity of M31 is consistent with the most recent theoretical models. Moreover, the fact that 73$\%$ of P01’s action method solutions do not fall within our 68.3$\%$ confidence ellipse suggests that our measurement has sufficient accuracy to provide meaningful constraints.
on the allowed solution space of the Local Group orbits and its history.

### 4.2. Local Group Mass

In § 3.1 we calculated that the minimum mass \( M = M_{\text{M31}} + M_{\text{MW}} \) required for a bound orbit is \( M_{\text{bind, min}} = 1.72^{+0.22}_{-0.25} \times 10^{12} M_\odot \), and that for a bound orbit the timing argument implies \( M = 5.58^{+0.55}_{-0.72} \times 10^{12} M_\odot \). These results are based on point-mass dynamics, where the point masses are proxies for entire the Milky Way subgroup of galaxies and the entire M31 subgroup of galaxies (i.e., the parent galaxy plus its satellites), respectively. Only a negligible fraction of the light in the Local Group comes from galaxies that are not part of either of these subgroups (see Table 2). Therefore, the mass \( M \) is a proxy for the total mass of the Local Group.

It is of interest to compare our mass estimates to those derived using independent arguments. Kochanek (1996) modeled the mass distribution of the Milky Way using equilibrium models for the velocities of Milky Way satellites, with the circular velocity of the disk and the escape velocity of stars in the solar neighborhood as additional constraints. This yielded a fairly well constrained mass of \( (0.5 \pm 0.1) \times 10^{12} M_\odot \) inside of 50 kpc. However, the total Milky Way mass depends on the extent of the dark halo, which is poorly constrained by any data. Kochanek’s solutions therefore allowed total masses anywhere from \( (1.5 - 5.0) \times 10^{12} M_\odot \) (see his Fig. 7). Wilkinson & Evans (1999) obtained a similarly large range from their models, \( M = 1.9^{+1.6}_{-1.7} \times 10^{12} M_\odot \), for the same reason. Both of these studies used rather arbitrarily parameterized density profiles. Klypin et al. (2002, hereafter K02) improved this situation by restricting the discussion to models with \( \Lambda \)CDM cosmologically motivated density profiles and concentrations. This yielded a much more tightly constrained total mass. Their favored solution (their model A1) has a total virial mass of \( 1.0 \times 10^{12} M_\odot \). The highest mass model that is still consistent with the observational and theoretical constraints (their model A4; see also Besla et al. 2007) has a total virial mass of \( 2.0 \times 10^{12} M_\odot \).

Evans & Wilkinson (2000) and Evans et al. (2000) modeled the mass distribution of M31 using equilibrium models for the velocities of M31 satellites and halo tracers. This yielded \( M = \left( 0.8^{+0.2}_{-0.3} \right) \times 10^{12} M_\odot \), suggesting that M31 is less massive than the Milky Way. However, as for the Milky Way modeling, the allowed mass range was large due to uncertainties in the dark halo extent. Again, K02 improved this situation by imposing theoretical constraints from \( \Lambda \)CDM modeling. This yielded a favored model (their model B1) with a total virial mass of \( 1.6 \times 10^{12} M_\odot \). The ratio \( M_{\text{M31}}/M_{\text{MW}} = 1.6 \) for the favored models in the K02 study (this implies \( f_{\text{M31}} = 0.62 \), as defined in § 2.3). This is similar to the value implied by the ratio of the galaxy’s circular velocities and the Tully-Fisher relation, \( (250/220)^{0.6} = 1.67 \) (Einasto & Lynden-Bell 1982).

K02 did not explore what maximum mass might still be consistent with the observational data for M31. However, to the lowest order one may guess that the situation is similar to that for the Milky Way, where the highest allowed mass is twice the favored mass. The maximum Local Group mass for the K02 models is therefore \( 5.2 \times 10^{12} M_\odot \), while the favored mass is \( M = 2.6 \times 10^{12} M_\odot \). This assumes that the derived virial masses of the Milky Way and Andromeda apply to their entire subgroups of satellites. This is reasonable, given the uncertainties already inherent in the estimates. The largest satellites of both subgroups (the Large Magellanic Cloud and M33, respectively) have \( \lesssim 10\% \) of the luminosity of their parent galaxy, and most other satellites contribute \( \lesssim 1\% \). Both the favored and the maximum mass of K02 exceed the value \( M_{\text{bind, min}} = 1.72^{+0.22}_{-0.25} \times 10^{12} M_\odot \) derived in § 3.1. This suggests that the Milky Way and M31 are indeed a bound system, as is usually assumed.

We showed that the timing argument for a bound M31–Milky Way system implies a mass \( M = 5.58^{+0.85}_{-0.72} \times 10^{12} M_\odot \). This is consistent with the maximum mass allowed by the K02 models but not with the favored mass. Even the tail of the probability distribution for \( M_{\text{timing}} \) in Figure 3 does not go as low as \( M = 2.6 \times 10^{12} M_\odot \). The best agreements are obtained for the case of nearly radial orbits and a small M31 distance. For example, \( V_{\text{tan}} = 0 \) and \( D = 700 \) kpc yield \( M_{\text{timing}} = 4.4 \times 10^{12} M_\odot \). But while this \( V_{\text{tan}} \) is consistent with our measurements, such a low distance is almost 2 \( \sigma \) away from the value \( D = 770 \pm 40 \) kpc inferred using a wide range of methods (Holland 1998; Joshi et al. 2003; Walker 2003; Brown et al. 2004; McGaughie et al. 2005; Ribas et al. 2005).

The timing argument provides a rather simplistic view of the evolution of a binary galaxy in a cosmological context. Several authors have therefore quantitatively studied its accuracy. Models that address the gravitational influence and torques of structures outside of the Local Group have generally concluded that these do not significantly bias the mass estimates obtained from the timing argument (Raychaudhury & Lynden-Bell 1989; Peebles et al. 1989, 2001; Pasetto & Chiosi 2007; see also § 4.1). However, these models generally treat individual galaxies as point masses. So this does not address the fact that the galaxies themselves assemble hierarchically over time.

To include hierarchical assembly it is necessary to perform more detailed dynamical calculations. Kroeker & Carlberg (1991) studied the accuracy of the timing argument by examining binary galaxies found in an \( N \)-body simulation of a closed CDM universe. They found that when \( V_{\text{tan}} \) is available, the timing argument provides an unbiased estimate of the total mass (measured in two spheres, centered on each galaxy, of radii one-half the intergalaxy separation). But estimates based on radial orbits yielded masses that were on average too low by a factor \( \sim 1.7 \). They also found that the galaxies must be bound for the timing argument to work, since it overestimates the actual mass of unbound pairs. The independent mass estimates of the Milky Way and M31 discussed above suggest that the galaxies are in fact bound, so this should not be an issue here. Kroeker & Carlberg also show that the timing argument may not work well for pairs that are not isolated. This too should not be much of an issue for the M31–Milky Way system, given that the Sculptor, M81, and Maffei groups are all some 3 Mpc away.

Goldberg (2001) reached somewhat different conclusions than Kroeker & Carlberg (1991). He modeled binary galaxies using a perturbative least action approach in which the galaxies are part of a continuous fluid that collapses over the course of the simulation. The results were cross-validated against an \( N \)-body simulation, with consistent results. From his calculations he concluded that the timing argument tends to overestimate the total mass of a pair by a factor of \( \sim 2 \). The reason for the discrepancy between this result and that of Kroeker & Carlberg is unclear. However, Goldberg’s calculations are quite idealized, while Kroeker & Carlberg’s calculations are now quite dated (in terms of both numerical sophistication and underlying cosmology). A more modern theoretical investigation of the accuracy of the timing argument was therefore presented recently by Li & White (2008).

Li & White (2008) identified galaxy pairs in the so-called Millennium Simulation with properties similar to the Milky Way–M31

\[ \text{\textsuperscript{2} This paper came to our attention after the original submission of our own work.} \]
system. The high quality and detail of this cosmological simulation provide excellent statistics, with thousands of pairs available for study. They found that the radial-orbit timing mass estimator provides an unbiased estimate of the total mass of a pair (defined as the sum of the \( M_{200} \) values, where \( M_{200} \) is the mass inside the sphere over which the mean density is 200 times that of the universe at large). With their preferred selection cuts, they found the ratio of the true to the estimated mass to be \( A = 0.99 \pm 0.41 \), where we transformed their quoted interquartile range to a traditional Gaussian dispersion. The simulations do not confirm the finding of Kroeker & Carlberg (1991) that the bias in the estimate depends on \( V_{\text{tan}} \), but they do indicate that the dispersion in the estimate increases with \( V_{\text{tan}} \). Either way, the radial-orbit analysis of Li & White is reasonable for the Milky Way–M31 system, since we have found that a radial orbit is consistent with the available observational constraints. The calculated “theoretical uncertainty” exceeds the uncertainties calculated here (see Fig. 3), which result from propagation of observational errors. This theoretical uncertainty therefore drives the accuracy with which the Local Group mass is known from the timing argument. The preferred Local Group mass of K02 corresponds to a ratio \( A = 0.47 \). This is 1.2 \( \sigma \) away from timing mass that we have calculated (with \( \sigma \) being the quadrature sum of the theoretical and observational uncertainties). Therefore, the two results are quite consistent. K02 quote a mass uncertainty of a factor \( n \approx 2 \), which is not too dissimilar from the timing mass uncertainty calculated by Li & White (2008). Therefore, it is not a priori clear which estimate is to be preferred.

### 4.3. Local Group Turnaround Radius

An independent mass estimate is obtained from the turnaround radius \( r_0 \) of the Local Group, defined as the distance from the Local Group barycenter at which galaxies have a radial velocity of zero (e.g., Lynden-Bell 1981). Using the same Keplerian formalism as in § 3.1, galaxies on the turnaround surface have \( \eta = \pi \) and \( V_{\text{rad}} = 0 \). Equation (10) therefore gives that

\[
r_0 = \left[ \frac{GM(t/\pi)^2}{3} (1 + e) \right]^{1/3}, \tag{13}
\]

where, as before, \( t \) is the age of the universe and \( r_0 \) is usually evaluated for radial orbits (\( e = 1 \)). Figure 3 shows the probability distribution of the predicted \( r_0 \) thus obtained, with \( M \) taken from the timing argument. The inferred \( 1 \sigma \) confidence interval around the median is \( r_0 = 1.56^{+0.08}_{-0.07} \) Mpc.

The \( r_0 \) predicted from the M31–Milky Way timing argument can be compared to the observationally inferred value, \( r_0 = 0.94 \pm 0.10 \) Mpc (e.g., Karachentsev et al. 2002). These values are not consistent. Since \( r_0 \propto M^{1/3} \), the observed \( r_0 \) implies a Local Group mass of only \( M = (1.3 \pm 0.3) \times 10^{12} M_\odot \). Similar results are obtained when this method is applied to other nearby groups (Karachentsev et al. 2005). This mass is lower than that implied by the timing argument (as stressed previously by Lynden-Bell 1999), and it is also lower than that implied by almost all studies of the individual masses of the Milky Way and M31 (see § 4.2). Moreover, comparison of this mass to \( M_{\text{bind, min}} \) (§ 3.1) suggests that M31 and the Milky Way then do not form a bound pair. This would make the Local Group little more than a chance superposition of two spiral galaxies. Such a configuration has fairly low a priori probability, given the local density of spiral galaxies (van den Bergh 1971).

The agreement between the observed and predicted turnaround radii improves if the galaxies defining the turnaround surface are not on radial orbits. A value \( e = 0.2 \) in equation (13) would yield perfect agreement. However, the corresponding orbits are then nearly circular, and this would produce a considerable thickness in the zero-velocity surface, which is inconsistent with observations (Lynden-Bell 1999). So a more reasonable conclusion may be that mass estimates based on the turnaround radius are systematically biased toward low values. Direct evidence for this comes from the action modeling of, e.g., Peebles et al. (2001). They models reproduce both the distances and redshifts of the galaxies in the outer regions of the Local Group (see Table 2), despite the use of a Local Group mass \( M = 5.16 \times 10^{12} M_\odot \) that significantly exceeds the mass implied by equation (13). This suggests that the isolated collapse picture on which the concept of a turnaround surface is based may not be suitable for the Local Group. The underlying reason may be that the dynamical structure near the edges of the Local Group is significantly influenced by structures in the mass distribution on larger scales. It should also be noted that even in idealized models the zero-velocity surface is not actually expected to be a sphere, but an elongated ellipsoid (e.g., Fig. 6 in Peebles et al. 1989). This is not generally taken into account in observational determinations of \( r_0 \).

### 5. Conclusions

We estimated the transverse motion of M31 under the assumption that the satellites of M31 follow the motion of M31 through space, and under the assumption that the galaxies in the outer parts of the Local Group follow the motion of the Local Group barycenter through space. The first method was applied independently to a sample of 17 satellites with known line-of-sight velocities, and to the two satellites M33 and IC 10 with known proper motions. The second method was applied to a sample of five galaxies near the Local Group turnaround radius (and we showed that the inclusion of six more distant galaxies does not significantly affect the results). The results from the different methods are mutually consistent and successfully recover the known line-of-sight velocity of M31. The weighted average heliocentric transverse velocity of M31 from the different methods in the west and north directions are found to be \( \langle v_w \rangle = -78 \pm 41 \) km s\(^{-1}\) and \( \langle v_N \rangle = -38 \pm 34 \) km s\(^{-1}\).

We used the known line-of-sight velocity with the newly inferred transverse velocity to determine the radial and tangential galactocentric velocity components of M31. We used a Bayesian analysis to obtain the statistical probability distribution for \( V_{\text{tan}} \), properly corrected for observationally induced errors and biases. The results are that \( V_{\text{rad}} = -130 \pm 8 \) km s\(^{-1}\) and that the probability distribution for \( V_{\text{tan}} \) has a median value of 42 km s\(^{-1}\) and a 1 \( \sigma \) confidence interval \( V_{\text{tan}} \leq 56 \) km s\(^{-1}\). A purely radial orbit is consistent with the data at this confidence level. These velocities are consistent with the predictions of the most recent action method models for the history of the Local Group and have small enough errors that they can start to meaningfully constrain the full solution space allowed by these models.

We used the M31 velocity vector to constrain the relative M31–Milky Way orbit. The minimum mass required for a bound orbit is \( M_{\text{bind, min}} = 1.72^{+0.26}_{-0.25} \times 10^{12} M_\odot \). If the orbit is indeed bound, then the timing argument combined with the known age of the universe implies that \( M = 5.58^{+0.72}_{-0.67} \times 10^{12} M_\odot \). This is consistent with the mass range suggested by cosmologically motivated models for the individual structure and dynamics of M31 and the Milky Way, respectively. However, the timing mass is on the high end of the allowed range, with the most favored models in the study of K02 yielding a Local Group mass of only \( 2.6 \times 10^{12} M_\odot \). This indicates that the M31 and the Milky Way are indeed bound, but that their total mass could be lower than suggested by the timing argument. Li & White (2008) performed
a theoretical calibration of the timing argument and found that while the timing argument mass is unbiased, it does have a theoretical dispersion of 41%. Therefore, it is not statistically implausible that for the specific case of the Milky Way—M31 system the timing argument mass could be an overestimate by a factor of ~2. The method of estimating the Local Group mass based on the size of the turnaround (zero-velocity) radius yields systematically lower masses than other methods and is in fact not consistent with a bound nature for the M31–Milky Way orbit. This and other arguments suggest that this method yields incorrect masses that are systematically biased low.

The M31 transverse velocity implies that M33 is in a tightly bound orbit around M31. The calculations of L05 indicate that for 82% of Monte Carlo samplings from the error ellipse, more tidal deformation of M33 would have been expected than is observed. However, this assumes that $M_{\odot} = (2.6-3.4) \times 10^{12} M_{\odot}$. The percentage is lower, and the agreement between observational and theoretical constraints on the M31 transverse velocity is better, if the M31 mass is as low as 1.6 \times 10^{12} M_{\odot}, as advocated by K02. Nonetheless, our results indicate that some tidal deformation of M33 could certainly have occurred. So it will be worthwhile to perform more deep searches for tidal tails and structures in the outer regions of M33. The estimates of the Local Group timing mass do not change significantly if the theoretical constraints from the L05 study of M33 structure are strictly enforced.

The transverse velocity inferred for M31 (the weighted average in Table 3) corresponds to a proper motion $\mu_{\alpha} \equiv -\dot{\alpha} \cos \delta = -21.5 \pm 11.1 \mu \text{as yr}^{-1}$ and $\mu_{\delta} \equiv \delta = -10.4 \pm 9.3 \mu \text{mas yr}^{-1}$ at a distance $D = 770$ kpc. It will be difficult to obtain an accurate proper-motion measurement in the near future that will rival the accuracy of this. The most accurate Hubble Space Telescope proper-motion measurements for any Local Group galaxy (for the Large and Small Magellanic Clouds; Kallivayalil et al. 2006a, 2006b) have errors of 50–80 $\mu$as yr$^{-1}$. VLBI measurements of water masers can provide errors of only 5–10 $\mu$as yr$^{-1}$ (Brunthaler et al. 2005, 2007). This is actually not much better than what we have already presented here. Moreover, no water masers are known in M31 to which this technique can be applied, and, at present detection limits, maybe none should be expected (Brunthaler et al. 2006). Therefore, a high-accuracy measurement of the proper motion of M31 will have to await future generations of astrometric satellites. However, even SIM or Gaia measurements will at best have uncertainties that are only a few times smaller than those reported here (see § 12 of Unwin et al. 2008), and moreover, results are not expected from these satellites for at least another decade.

It may be possible to improve the results presented here by using a larger number of tracers of the M31 velocity. If the sample of M31 satellites with water maser proper motions can be increased from 2 to ~8, then this would halve the uncertainty in the average result from the method in § 2.2. However, this may not be possible. Water masers are often associated with regions of star formation, whereas most M31 satellites are early-type dwarf ellipticals or spheroidals (see Table 1). Even in the gas-rich satellites the prospects for new water maser discoveries are not good (Brunthaler et al. 2006). Therefore, the number of satellites for which water maser proper motions can be obtained is fundamentally limited. Alternatively, it may be possible to increase the number of tracers at large distances from M31 for which line-of-sight velocities are available. A significant increase would be needed (from 17 to ~68) to merely halve the uncertainties in our result from § 2.1. While new satellites of M31 continue to be discovered on a regular basis (e.g., Zucker et al. 2007; Ibata et al. 2007), this is unlikely to significantly affect the statistics. Individual red giant branch stars in the outer halo of M31 may be more promising (e.g., Gilbert et al. 2006), since it is possible, at least in principle, to obtain line-of-sight velocities for large numbers of such stars.

We thank Nitya Kallivayalil and Gurtina Besla for a careful reading of this paper and Anatoly Klypin, Frank van den Bosch, Lars Hernquist, and T. J. Cox for useful discussions. We thank the anonymous referee for helpful suggestions that improved the presentation of the paper. We made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion Laboratory, Caltech.
