Prevalence and anatomical location of muscle tenderness in adults with nonspecific neck/shoulder pain

Lars L Andersen¹, Klaus Hansen¹, Ole S Mortensen¹,² and Mette K Zebis¹,³

Abstract
Background: Many adults experience bothersome neck/shoulder pain. While research and treatment strategies often focus on the upper trapezius, other neck/shoulder muscles may be affected as well. The aim of the present study is to evaluate the prevalence and anatomical location of muscle tenderness in adults with nonspecific neck/shoulder pain.

Methods: Clinical neck/shoulder examination at two large office workplaces in Copenhagen, Denmark. 174 women and 24 men (aged 25-65 years) with nonspecific neck/shoulder pain for a duration of at least 30 days during the previous year and a pain intensity of at least 2 on a modified VAS-scale of 0-10 participated. Exclusion criteria were traumatic injuries or other serious chronic disease. Using a standardized finger pressure of 2 kg, palpable tenderness were performed of eight anatomical neck/shoulder locations in the left and right side on a scale of ‘no tenderness’, ‘some tenderness’ and ‘severe tenderness’.

Results: In women, the levator scapulae, neck extensors and infraspinatus showed the highest prevalence of severe tenderness (18-30%). In comparison, the prevalence of severe tenderness in the upper trapezius, occipital border and supraspinatus was 13-19%. Severe tenderness of the medial deltoid was least prevalent (0-1%). In men, the prevalence of severe tenderness in the levator scapulae was 13-21%, and ranged between 0-8% in the remainder of the examined anatomical locations.

Conclusions: A high prevalence of tenderness exists in several anatomical locations of the neck/shoulder complex among adults with nonspecific neck/shoulder pain. Future research should focus on several neck/shoulder muscles, including the levator scapulae, neck extensors and infraspinatus, and not only the upper trapezius.

Trial Registration: ISRCTN60264809

Background
A high prevalence of upper extremity pain exists among adults working in sedentary occupations [1]. Neck/shoulder pain is a risk factor for long-term sickness absence among white-collar workers [2], and every other office worker experience neck/shoulder pain on a weekly basis [1,3]. Pain symptoms are believed to worsen in response to prolonged static muscle activity and/or repetitive job tasks [4,5], causing muscle metabolic disturbances [6].

Kaergaard and coworkers found a strong correlation between reported neck/shoulder pain and clinically verified muscle tenderness [7]. Especially, tenderness of the upper trapezius muscle often co-exists with neck/shoulder pain [6,8,9]. The upper trapezius muscle is due to its bulky and superficial nature - well suited for clinical research, and displays clear physiological differences between symptomatic and non-symptomatic individuals regarding electromyographic activity [10,11], muscle strength [10,11], muscle fiber morphology [12], stem cell content [13], and intramuscular metabolites [14]. In spite of the inordinate focus on the upper trapezius, other muscles of the neck/shoulder complex may...
be affected as well - and should therefore not be overlooked when treating neck/shoulder pain.

Ohlsson and coworkers developed a clinical protocol for diagnosing disorders of the neck, shoulder and arm - e.g. tension neck syndrome, frozen shoulder and lateral epicondylitis [15]. Juul-Kristensen and coworkers extended this protocol, and included the diagnosis of trapezius myalgia - frequent neck pain with co-existing tenderness and tightness of the upper trapezius muscle [8]. The overall prevalence of these disorders is low to modest [8,15]. Together these studies show that many people experience non-specific neck/shoulder pain, i.e. pain in absence of the aforementioned clinically diagnosed disorders.

The aim of the present study is to evaluate the prevalence and anatomical location of muscle tenderness among adults with nonspecific neck/shoulder pain, but without traumatic injuries or other serious chronic disease.

**Methods**

**Participants**

We obtained data for this prevalence-study as part of a randomized controlled trial [16], register number ISRCTN60264809. A screening questionnaire to locate generally healthy adults with frequent nonspecific neck/shoulder pain went out to 1094 employees from two large office companies, and 653 replied (60%). Figure 1 outlines the flow of participants. Exclusion criteria for participation in the investigation were a medical history of cardiovascular or cerebrovascular accident or disease (n = 8), fibromyalgia (n = 1), rheumatoid arthritis (n = 7), cervical disc herniation (n = 5), whiplash (n = 18), pregnancy (n = 16), working less than 30 hours per week (n = 69), performing more than 2 hours per week of vigorous physical exercise (n = 95), or declining to participate in the study (n = 206). Based on the screening questionnaire replies employees with an average neck/shoulder pain intensity during the last 3 months of at least 2 on a modified VAS scale of 0-10 [17,18], neck/shoulder tenderness of at least ‘some’ (scale of ‘no’, ‘some’ and ‘severe’ tenderness), and a duration of at least 30 days with neck/shoulder pain during the last year [19] were invited for a clinical neck/shoulder examination (n = 305) (47% of those who replied to the questionnaire). Out of the 305 invited 258 presented for the examination.

To locate details that were not evident from the screening questionnaire the clinical examination started with an interview on medical history and pain symptoms, measurement of blood pressure, Hawkins test for subacromial impingement [20], and Spurling’s foramen compression test for cervical radiculopathy [21]. Exclusion criteria during the clinical examination were hypertension above 160/100, a positive Hawkins test, a positive Spurling’s test or a medical history of traumatic neck/shoulder injuries or other serious chronic disease. This procedure lead to exclusion of 60 participants;
hypertension above 160/100 (n = 6), severe neck/shoulder trauma (n = 9), subacromial impingement syndrome (n = 2), cervical radiculopathy (n = 2), myasthenia (n = 1), severe pain due to osteoarthritis (n = 2), disc herniation (n = 1), withdrawal of consent (n = 5). Further, we asked the participants if they had experienced neck/shoulder pain frequently during the previous year. This lead to exclusion of another 31 participants, who had experienced only a brief period of pain during the previous year, for example, due to hectic sporting activities. The remaining 198 generally healthy adults with frequent nonspecific neck/shoulder pain formed the basis for this study.

Examination for tenderness
A team of four trained examiners (physical therapists) performed the examination for tenderness. The examiners were blinded to the questionnaire replies on self-reported pain symptoms. The examination built on a previously described procedure from our laboratory by Juul-Kristensen and coworkers, who reported good reliability of palpable tenderness scores of the neck/shoulder muscles [8]. Due to the subjective nature of manual palpation tests, we used several strategies to improve the internal validity of our study. For manual palpation tests to be valid a standardized finger pressure needs to be applied. Using a scale and a pinch grip dynamometer, the examiners practiced a finger-pressure (thumb, index finger, and middle finger, respectively) and pinch grip (i.e. pressing the thumb against the index finger) of 2 kg - a procedure which was repeated frequently between examinations during the study period. Repeating this procedure frequently all four examiners were able to apply a finger pressure and pinch grip ranging from 1.8 to 2.2 kg without looking at the scale or dynamometer. Twenty volunteers from our department participated during a pilot week for the examiners to become mutually calibrated with the manual palpation procedure. At the end of the pilot week the inter-rater reliability for the tenderness scores was high between all four examiners (ICC > 0.70). Further, as previously reported, test-retest reliability of the tenderness score in 64 of the present participants, who was re-tested on a later occasion, was good (Intraclass Correlation Coefficient (ICC) = 0.88) [22].

The examiners determined tenderness by deep palpation of eight anatomical neck/shoulder locations on the left and right side. Based on the participants response and feedback during the palpation, the examiner used a score of 0-2, corresponding to ‘no tenderness’, ‘some tenderness’ or ‘severe tenderness’, respectively, for each anatomical location (Figure 2):
Occipital border
Using the thumb, the examiners palpated the entire occipital border along the linea nuchalis superior - the tenderest part along the border defined the score. The examiner supported the forehead of the participant with the contralateral hand.

Upper trapezius
Using a pinch grip with the thumb and index finger, the examiner palpated the upper trapezius from the acromion to the border of neck - not including the vertical part of the neck. The tenderest part along the trapezius determined the tenderness score.

Levator scapulae insertion
Using the thumb, the examiner palpated the insertion-spot of the levator scapulae at the superior angle of scapulae.

Levator scapulae
Using the index finger with reinforcement from the middle finger, the examiner palpated the levator scapulae from the insertion of the scapulae until the sixth cervical vertebrae. The tenderest part along the levator scapulae defined the tenderness score.

Neck extensors
Using the index- and middle finger, the examiner palpated the neck extensor muscles all the way from the sixth cervical vertebrae to below the occipital border. The examiner supported the forehead of the participant with the contralateral hand. The tenderest part along the extensor muscles defined the tenderness score.

Supraspinatus
Using the index finger with reinforcement from the middle finger, the examiner palpated the hollow where the acromion and clavicle joins.

Infraspinatus
Using the index finger with reinforcement from the middle finger, the examiner palpated the spot where the infraspinatus is superficial - below the posterior deltoid lateral to the medial trapezius. To accurately locate the infraspinatus the examiner first asked the participant to actively perform an external rotation of the arm and then to relax.

Medial deltoid
Using the index and middle fingers, the examiner palpated the medial deltoid from below the acromion to the insertion at humerus. The tenderest part along the muscle determined the tenderness score.

Statistics
We used the SAS statistical software (SAS institute, Cary, NC, version 9.2) for all analyses. Using the GENMOD procedure, one-way analysis of variance (ANOVA) determined differences in tenderness scores between the examined anatomical locations (averaged for left and right side). We also performed the ANOVA to determine differences in tenderness scores between genders.

Further, we calculated the weighted kappa coefficient between the tenderness scores to test for possible clustering of tenderness between anatomical locations.

Finally, we performed a multiple regression analysis with backward elimination to determine which anatomical location was most strongly correlated to perceived pain intensity. Tenderness scores of the 8 anatomical locations - averaged for left and right side - were entered in the model as explanatory variables. The outcome was questionnaire-based neck/shoulder pain intensity during the last week (scale 0-10). The analysis was controlled for gender.

Results
Table 1 shows demographics, clinical and work-related characteristics of the participants. The duration and intensity of reported neck/shoulder pain was high, and participants spent most of their working time at a computer. The women had higher tenderness scores in the neck/shoulder muscles and lower blood pressure than the men.

Table 2 shows the prevalence of tenderness and average tenderness scores with significance levels from the ANOVA between anatomical locations and genders. For women, the prevalence of tenderness (some + severe) was above 50% in all of the examined anatomical locations but the deltoid muscle. The prevalence of severe tenderness ranged between 18-30% in the infraspinatus, neck extensors and levator scapulae, and ranged between 13-19% in the upper trapezius, occipital border, and supraspinatus. Only 1 out of 174 woman experienced severe tenderness in the medial deltoid. Because the prevalence of severe tenderness was comparable in the levator scapulae muscle and levator scapulae insertion (Table 2) we simply use the term “levator scapulae” in the following.

The ANOVA also showed that average tenderness scores in men were significantly lower than in women in the neck extensors (P < 0.0001), infraspinatus (P < 0.0001), upper trapezius (P = 0.03), and supraspinatus (P = 0.03). In men, the prevalence of severe tenderness in the levator scapulae was 13-21%, and ranged between 0-8% in the remainder of the examined anatomical locations.

On an exploratory basis, we also performed the ANOVA for tenderness with side (left and right) as a covariate. However, there was no main effect of side, i.e. tenderness scores were not significantly different between the left and right sides.
Table 3 shows that the association of tenderness between the examined anatomical locations was generally weak. The left and right side of each examined anatomical location generally showed the highest level of agreement (0.33 - 0.54).

The multiple regression analysis with backward elimination showed that tenderness in the levator scapulae ($\beta = 0.22$, $P < 0.01$), infraspinatus ($\beta = 0.16$, $P < 0.05$) and deltoid ($\beta = 0.17$, $P < 0.05$) remained significant in the final model for neck/shoulder pain intensity.

Discussion

Our study shows a high prevalence of tenderness in several anatomical locations of the neck/shoulder complex among generally healthy adults with nonspecific neck/shoulder pain. Tenderness scores were highest in the levator scapulae and neck extensors in women, and highest in the levator scapulae in men.

The upper trapezius is a large superficial muscle extending from the occipital bone and cervical vertebrae to the acromion and lateral part of the clavicle [23]. Much research on neck/shoulder pain has focused on the upper trapezius muscle [6,8,9]. Although trapezius myalgia - chronic tenderness and tightness of the upper trapezius muscle - is the most common clinical diagnosis in adults with self-reported neck/shoulder pain [8], our results show that severe tenderness more commonly occurs in the levator scapulae, neck extensors and infraspinatus. Although the levator scapulae, neck extensors and infraspinatus are smaller than the trapezius, future research should focus also on these muscles and not only the upper trapezius.

Table 1 Demographics, clinical and work-related characteristics

|                        | Women (n = 174) | Men (n = 24) | P-value |

| Duration of office work, years | 11 (10)      | 12 (11)     | 0.64    |

Demographics, clinical and work-related characteristics of the 198 generally healthy office workers with frequent neck/shoulder pain. Total Tenderness Score is the sum of tenderness scores of ‘no’ (= 0), ‘some’ (= 1), and ‘severe’ (= 2) tenderness of the 8 investigated neck/shoulder anatomical locations of the left and right side (scale 0-32).

The levator scapulae origins from the upper cervical vertebrae, extend along the back of the neck and inserts at the medial angle of scapulae [23]. The neck extensor muscles - e.g. semispinalis and splenius - extend along the back of the neck [23]. Together the levator scapulae and neck extensor muscles provide stability and prevent forward flexion and rotation of the neck during static work positions, e.g. at the computer. Although our study did not investigate the underlying mechanisms of tenderness, prolonged muscle fiber activation of the levator scapulae and neck extensors during long hours of computer work may lead to development of pain and tenderness [6].

Our study shows that a high prevalence of infraspinatus tenderness also exists in adults with nonspecific neck/shoulder pain. The infraspinatus externally rotates the shoulder and provides stability and motion of the arm during many work tasks [24]. During most types of computer work, e.g. when using the mouse or typing at the keyboard, the humerus is slightly externally rotated, which may put excessive stress on the infraspinatus [25] and potentially lead to development of tenderness.

Although more sophisticated methods for research studies exists, e.g. digitalized pressure algometry [26], physical therapists primarily rely on their hands for manually diagnosing upper extremity disorders. As many of the investigated neck/shoulder muscles overlap anatomically - e.g. the trapezius muscles covers both the suprasinatus and levator scapulae - completely differentiating tenderness between muscles may not be possible. Nevertheless, the low kappa coefficients between the investigated anatomical neck/shoulder locations suggest
that using the present method of manual palpation only minor overlap of tenderness exists. The weighted kappa coefficients of table 3 show no systematic clustering of tenderness among the different anatomical locations of the neck/shoulder complex. As the method of manual palpation using a pre-learned pressure provides quick and reliable information on muscle tenderness [8,16], therapists may use the present screening tool to determine specific muscle tenderness in patients with neck/shoulder pain and thereby more efficiently target rehabilitation exercises.

Our study is the first to report on the prevalence and anatomical location of palpable muscle tenderness among men with neck/shoulder pain. In spite of the limited male sample size, we showed clear gender differences for the prevalence of examiner-verified tenderness in spite of comparable subjective pain symptoms. While many women suffered from severe tenderness in several of the investigated muscles, the levator scapulae was the primary source of severe tenderness in men. Women generally have lower pressure pain thresholds than men [27,28], likely due to more potent neural inhibitory control mechanisms in men [29]. Thus, using a standardized finger pressure of 2 kg as in our study may lead to stronger sensitivity of pain in women than men in spite of comparable questionnaire replies on neck/shoulder pain intensity. This suggests that application of these results to the general population should take gender into account.

The multiple regression analysis showed that tenderness of the levator scapula, infraspinatus and deltoid were significantly related to perceived neck/shoulder pain intensity. This suggests that application of these results to the general population should take gender into account.

Table 2 Prevalence of tenderness

| Site                        | Women (n = 174) | Men (n = 24) | Some | Severe | Total | Between-site difference | Some | Severe | Total | Between-site difference |
|-----------------------------|-----------------|--------------|------|--------|-------|-------------------------|------|--------|-------|-------------------------|
| Neck extensors              |                 |              | 48.9 | 27.6   | 76.4  | 1.01 (0.05)             | 50.0 | 4.2    | 54.2  | 0.56 (0.10)             |
|                            |                 |              | 47.1 | 25.3   | 72.4  | 1.01 (0.05)             | 45.8 | 4.2    | 50.0  | 0.56 (0.10)             |
| Levator scapulae insertion  |                 |              | 52.3 | 26.4   | 78.7  | 0.99 (0.04)             | 75.0 | 16.7   | 91.7  | 0.99 (0.04)             |
|                            |                 |              | 57.5 | 17.8   | 75.3  | 1.01 (0.05)             | 66.7 | 12.5   | 79.2  | 1.01 (0.05)             |

|                            |                 |              | 56.9 | 22.4   | 79.3  | 1.01 (0.05)             | 54.2 | 20.8   | 75.0  | 1.01 (0.05)             |
| Infraspinatus               |                 |              | 32.8 | 30.5   | 63.2  | 0.89 (0.05)             | 29.2 | 29.2   | 58.4  | 0.89 (0.05)             |
|                            |                 |              | 54.3 | 22.1   | 76.4  | 0.89 (0.05)             | 29.2 | 29.2   | 58.4  | 0.89 (0.05)             |
| Upper trapezius             |                 |              | 60.3 | 12.6   | 73.0  | 0.89 (0.04)             | 50.0 | 8.3    | 58.3  | 0.89 (0.04)             |
|                            |                 |              | 60.9 | 16.1   | 77.0  | 0.89 (0.04)             | 58.3 | 4.2    | 62.5  | 0.89 (0.04)             |
| Occipital border            |                 |              | 55.2 | 13.8   | 68.9  | 0.84 (0.04)             | 45.8 | 4.2    | 50.0  | 0.84 (0.04)             |
|                            |                 |              | 56.3 | 14.9   | 71.3  | 0.84 (0.04)             | 58.3 | 8.3    | 66.7  | 0.84 (0.04)             |
| Supraspinatus               |                 |              | 39.7 | 19.0   | 58.6  | 0.74 (0.05)             | 41.7 | 4.2    | 45.8  | 0.74 (0.05)             |
|                            |                 |              | 44.3 | 12.6   | 56.9  | 0.74 (0.05)             | 50.0 | 0.0    | 50.0  | 0.74 (0.05)             |
| Medial deltoid              |                 |              | 12.1 | 0.6    | 12.6  | 0.10 (0.02)             | 0.0  | 0.0    | 0.0   | 0.10 (0.02)             |
|                            |                 |              | 5.8  | 0.0    | 5.8   | 0.00 (0.00)             | 8.3  | 0.0    | 8.3   | 0.00 (0.00)             |

Prevalence of ‘some tenderness’ and ‘severe tenderness’ - as well as the total prevalence of tenderness (total = some + severe; note that not all sums match due to rounding) - of 8 selected anatomical locations in the 198 generally healthy office workers with frequent neck/shoulder pain. The anatomical locations are ranked in descending order of the tenderness score for women. Average scores (0-2) are calculated as the average right and left score, where some tenderness = 1 and severe tenderness = 2. Between-location and between-gender differences were based on ANOVA’s of the tenderness scores (0-2).

*: sign.diff. from deltoidesus
#: sign.diff. from supraspinatus
$: sign.diff. from occipital border
£: sign.diff. from trapezius
&: sign.diff. from infraspinatus.

Andersen et al. BMC Musculoskeletal Disorders 2011, 12:169
http://www.biomedcentral.com/1471-2474/12/169
both showed a high prevalence of tenderness), the significant influence of deltoid tenderness on perceived pain intensity was unexpected. Speculatively, tenderness of the deltoid muscle may reflect referred pain from undiagnosed progressing disease, e.g. shoulder joint osteoarthritis. Altogether, tenderness of the levator scapulae, infraspinatus and deltoid appears to be interesting areas for future neck/shoulder research.

Limitations
A limitation is the small number of men (n = 24), which increases the risk of statistical type II errors. Also, the anatomical overlap of several neck/shoulder muscles - e.g. trapezius and supraspinatus - may weaken the ability to precisely determine tenderness of specific muscles. Further, the study would have been strengthened by measuring pressure pain threshold of all the investigated anatomical locations and relating this to the manual palpation scores. As manual palpation scores are prone to many errors, the inclusion of a calibrated team of trained examiners may have strengthened the study.

Although, the tenderness scale of ‘no’, ‘some’ and ‘severe’ tenderness does not allow for much sensitivity, it is easy to understand and use in practice. However, in hindsight, a greater resolution of the scale may have been valuable. Future validity- and reproducibility-studies should determine whether a higher resolution of the scale is feasible, e.g. a 5-point tenderness scale or a 100 mm VAS scale for perceived tenderness. It should be noted that the low weighted kappa values may result from using manual measurements and four examiners, and not necessarily because of a lack of clustering of tenderness. Referred pain - i.e. pain perceived at a location adjacent or distant from the injury’s origin - which is a common phenomenon in relation to neck and head pain [30], may have caused spreading of tenderness. Finally, the inclusion and exclusion criteria of our study confine the external validity to adults with nonspecific neck/shoulder pain without traumatic injuries or other serious chronic disease.

Conclusion
In conclusion, a high prevalence of tenderness in several anatomical locations of the neck/shoulder complex among adults with nonspecific neck/shoulder pain exists. Our results indicate that future research on neck/shoulder pain should focus on several muscles, including the levator scapulae, neck extensors and infraspinatus, and not only the upper trapezius.

Funding
Author LLA received a grant from the Danish Rheumatism Association (grant R68-A993) for this study.

Acknowledgements
We thank physiotherapist Charlotte Saervoll for assistance with the clinical examination. We also thank the students from the Metropolitan University College for practical help during the project.

Weighted kappa coefficients between the investigated neck/shoulder locations, pooled for men and women (n = 198).
Prevalence and anatomical location of muscle tenderness in adults with nonspecific neck/shoulder pain. BMC Musculoskeletal Disorders 2011; 12:169.

Submit your next manuscript to BioMed Central and take full advantage of:

• Convenient online submission
• Thorough peer review
• No space constraints or color figure charges
• Immediate publication on acceptance
• Inclusion in PubMed, CAS, Scopus and Google Scholar
• Research which is freely available for redistribution
