ABSTRACT

The first deep blank-field 450 \(\mu\)m map (1\(\sigma\) \(\approx\) 1.3 mJy) from the Submillimetre Common-User Bolometer Array-2 SCUBA-2 Cosmology Legacy Survey (S2CLS), conducted with the James Clerk Maxwell Telescope (JCMT) is presented. Our map covers 140 arcmin\(^2\) of the
Cosmological Evolution Survey field, in the footprint of the Hubble Space Telescope (HST) Cosmic Assembly Near-Infrared Deep Extragalactic Legacy Survey. Using 60 submillimetre galaxies detected at $\geq 3.75\sigma$, we evaluate the number counts of 450-µm-selected galaxies with flux densities $S_{450} > 5$ mJy. The 8 arcsec JCMT beam and high sensitivity of SCUBA-2 now make it possible to directly resolve a larger fraction of the cosmic infrared background (CIB, peaking at $\lambda \sim 200 \mu$m) into the individual galaxies responsible for its emission than has previously been possible at this wavelength. At $S_{450} > 5$ mJy, we resolve $(7.4 \pm 0.7) \times 10^{-2}$ MJy sr$^{-1}$ of the CIB at 450 µm (equivalent to $16 \pm 7$ per cent of the absolute brightness measured by the Cosmic Background Explorer at this wavelength) into point sources. A further $\sim 40$ per cent of the CIB can be recovered through a statistical stack of 24 µm emitters in this field, indicating that the majority ($\sim 60$ per cent) of the CIB at 450 µm is emitted by galaxies with $S_{450} > 2$ mJy. The average redshift of 450 µm emitters identified with an optical/near-infrared counterpart is estimated to be $\langle z \rangle = 1.3$, implying that the galaxies in the sample are in the ultraluminous class ($L_{\text{IR}} \approx 1.1 \times 10^{12} L_\odot$). If the galaxies contributing to the statistical stack lie at similar redshifts, then the majority of the CIB at 450 µm is emitted by galaxies in the luminous infrared galaxy (LIRG) class with $L_{\text{IR}} > 3.6 \times 10^{11} L_\odot$.

**Key words:** galaxies: high-redshift – cosmology: observations – submillimetre: galaxies.

1 INTRODUCTION

Fifteen years have passed since the first ‘submillimetre galaxies’ (SMGs) were discovered (Smail, Ivison & Blain 1997; Barger et al. 1998; Hughes et al. 1998), a high-redshift population ($z \sim 2$–3, Chapman et al. 2005; Aretxaga et al. 2007; Wardlow et al. 2011) with ultraluminous ($10^{12} L_\odot$) levels of bolometric emission, the bulk of which is emitted in the far-infrared and redshifted to submillimetre wavelengths at $z > 1$. The power of submillimetre surveys for exploring the formation phase of massive galaxies was recognized before their discovery (e.g. Blain & Longair 1993; Dunlop et al. 1994), and since their discovery, their importance as a cosmologically significant population has been established by many studies (e.g. Ivison et al. 2000, 2005, 2010; Smail et al. 2002; Dunlop et al. 2004; Coppin et al. 2008; Michałowski et al. 2010; Hainline et al. 2011; Hickox et al. 2012; and see Dunlop 2011, for a review). As such, SMGs provide challenging tests for models of galaxy formation, both in detailed ‘zoomed’ simulations as well as in cosmological theories (Baugh et al. 2005; Davé et al. 2010). However, our view of the SMG population remains incomplete.

In ground-based work, the majority of SMGs have – so far – mainly been selected in the 850 µm or 1 mm atmospheric windows (e.g. Coppin et al. 2006; Weiss et al. 2009; Austernmann et al. 2010; Scott et al. 2010), but this is far removed from the peak of the cosmic infrared background (CIB), which is at $\lambda \sim 200 \mu$m (Fixsen et al. 1998; Dole et al. 2006; Béthermin et al. 2010). The next available window closer to the CIB peak is at 450 µm, but the transmission of this window is just at best 50 per cent of the 850 µm window, making 450 µm SMG surveys challenging from ground-based sites. Submillimetre surveys working closer to the CIB peak are essential if we are to identify the galaxies responsible for its emission; the $S_{450}/S_{850}$ colours of sources identified in the very deepest (lensing assisted) submillimetre surveys (Blain et al. 1999; Knudsen, van der Werf & Kneib 2008) suggest that these sources contribute less than half of the CIB at 450 µm (and therefore even less at the actual peak).

The Balloon-borne Large Aperture Submillimetre Telescope (BLAST, Pascale et al. 2008) made progress by conducting a low-resolution submillimetre survey from the stratosphere at 250, 350 and 500 µm (Pascale et al. 2008; Devlin et al. 2009; Glenn et al. 2010). This work was taken forward by the Herschel Space Observatory, which carries an instrument that images in the same wavelength ranges as BLAST (the Spectral and Photometric Imaging Receiver; SPIRE), and has mapped hundreds of square degrees of the sky at 250–500 µm in a combination of panoramic and deep cosmological surveys (Eales et al. 2010, Oliver et al. 2010, 2012). However, the low-resolution and high-confusion limits of Herschel [full width at half-maximum (FWHM) $\sim 0.5$ arcmin at 500 µm, $\sigma_{\text{FWHM}} \approx 7$ mJy beam$^{-1}$, Nguyen et al. 2010] limit the fraction of the CIB that can be directly resolved, with 15 per cent resolved into individual galaxies at 250 µm and 6 per cent at 500 µm (Clements et al. 2010; Glenn et al. 2010; Béthermin et al. 2012a). Thus, there remains work to be done in identifying the galaxies that emit the CIB, and thus finally complete the census of dust-obscured activity in the Universe and its role in galaxy evolution.

Advances in submillimetre imaging technology are just now allowing us to take up the search once more, taking advantage of higher resolution possible with large terrestrial telescopes, and improved sensitivity and mapping capability in submillimetre detector arrays. The SCUBA-2 camera is the state of the art in submillimetre wide-field instrumentation (Holland et al. 2013). The camera, now mounted on the 15 m James Clerk Maxwell Telescope (JCMT), consists of 5000 pixels in both 450 and 850 µm detector arrays with an 8 arcmin field of view (16 times that of its predecessor, SCUBA). The increase in pixel number is the reward of developments in submillimetre detector technology; SCUBA-2 utilizes superconducting transition edge sensors to detect submillimetre photons, with multiplexed superconducting quantum interference device amplifiers handling read-out, analogous to an optical CCD. SCUBA-2 offers the capability to efficiently map large (degree-scale) areas, and has the sensitivity to simultaneously achieve deep (confusion limited) maps at both 450 and 850 µm. At 450 µm, the resolution attainable with the JCMT is a factor of $\sim 5$ times finer than the 500 µm resolution of Herschel, and the confusion limit is $\sim 7$ times fainter.
Here, we present results from early science observations of one of the seven components of the JCMT Legacy Survey;1 the SCUBA-2 Cosmology Legacy Survey (S2CLS).2 The goal of the S2CLS is to fully exploit SCUBA-2’s mapping capabilities for the purpose of exploring the high-redshift Universe. The S2CLS will cover several well-studied extragalactic ‘legacy’ fields, including the United Kingdom Infrared Deep Sky Survey Ultra Deep Survey field, the Cosmological Evolution field (COSMOS), the Extended Groth Strip, and the Great Observatories Origins Deep Survey (North) fields. We present the deepest blank-field map at 450 µm yet produced (in the COSMOS field), and measure the flux distribution and abundance of the extragalactic sources revealed within it. In Section 2, we describe the observations and data reduction technique, in Section 3, we calculate the 450 µm number counts and evaluate the contribution to the CIB at 450 µm. We briefly discuss and summarize our findings in Sections 4 and 5.

2 OBSERVATIONS AND DATA REDUCTION

Observations were conducted in Band 1 weather conditions ($\tau_{225\,\text{GHz}} < 0.05$) over 22 nights between 2012 January 23 and May 20 totalling 50 h of on-sky integration. The mapping centre of the SCUBA-2 COSMOS/CANDELS field is $\alpha = 10^h10^m29^s8, \delta = 02^\circ15'01''6$, chosen to be in the footprint of the Hubble Space Telescope (HST) CANDELS (Grogin et al. 2011; Koekemoer et al. 2011).3 A standard 3 arcmin diameter ‘daisy’ mapping pattern was used, which keeps the pointing centre on one of the four SCUBA-2 sub-arrays at all times during exposure.

2.1 Map making

Individual 30 min scans are reduced using the dynamic iterative map maker of the SMURF package (Jenness et al. 2011; Chapin et al. 2013). Raw data are first flat-fielded using ramps bracketing every science observation, scaling the data to units of pW. The signal recorded by each bolometer is then assumed to be a linear combination of: (a) a common mode signal dominated by atmospheric water and ambient thermal emission; (b) the astronomical signal (attenuated by atmospheric extinction) and finally (c) a noise term, taken to be the combination of any additional signal not accounted for by (a) and (b). The dynamic iterative map maker attempts to solve for these model components, refining the model until convergence is met, an acceptable tolerance has been reached, or a fixed number of iterations have been exhausted (in this case, 20). This culminates in time-streams for each bolometer that should contain only the astronomical signal, corrected for extinction, plus noise. The signal from each bolometer’s time stream is then re-gridded on to a map, according to the scan pattern, with the contribution to a given pixel weighted according to its time-domain variance (which is also used to estimate the $\chi^2$ tolerance in the fit derived by the map maker).

The sky opacity at JCMT has been obtained by fitting extinction models to hundreds of standard calibrators observed since the commissioning of SCUBA-2 (Dempsey et al. 2013). The optical depth in the 450 µm band was found to scale with the Caltech Submillimetre Observatory 225 GHz optical depth as: $\tau_{450} = 26.0(\tau_{225} - 0.0196)$. Note that this scaling is slightly different from the original SCUBA relations (see Archibald et al. 2002; Dempsey et al. 2012).

Up-to-date sensitivity formulae for the various mapping strategies can be found at the SCUBA-2 instrument page.4 Filtering of the time series is performed in the frequency domain, with band-pass filters equivalent to angular scales of $2 < \theta < 120$ arcsec (i.e. frequencies of $f = v/\theta$, where $v$ is the scan speed). The reduction also includes the usual filtering steps of spike removal (>10σ deviations in a moving boxcar) and DC step corrections. Throughout the iterative map making process, bad bolometers (those significantly deviating from the model) are flagged and do not contribute to the final map. Maps from independent scans are co-added in an optimal stack using the variance of the data contributing to each pixel to weight spatially aligned pixels. Finally, since we are interested in (generally faint) extragalactic point sources, we apply a beam matched filter to improve point source detectability, resulting in a map that is convolved with an estimate of the 450 µm beam. The average exposure time over the nominal 3 arcmin daisy mapping region (in practice there is usable data beyond this) is approximately 10 ks per 2 arcsec × 2 arcsec pixel.

We have verified that the noise scales with $(\sqrt{t_{\text{exp}}})^{-1}$ by sequentially co-adding individual scans and measuring the central rms value of the map at each stage. However, it is apparent that confusion noise is becoming significant, with the integrated noise falling off as $(\sqrt{t_{\text{exp}}})^{-1} + C$, where $C$ is the confusion limit. We estimate that $C \approx 1$ mJy based on the current fit.

2.2 Flux calibration

The flux calibration of SCUBA-2 data has been examined by analysing all flux calibration observations since Summer 2011 until the date of observation. The derived beam-matched flux conversion factor (FCF) has been found to be reasonably stable over this period, and the average FCFs agree (within error) to those derived from the subset of standard calibrators observed on the nights of the observations presented here. Therefore, we have adopted the canonical calibration of $\text{FCF}_{450} = 540 \pm 65$ Jy beam$^{-1}$ pW$^{-1}$ here. A correction of $\sim$10 per cent is included in order to compensate for flux lost due to filtering in the blank-field map. This is estimated by inserting a bright Gaussian point source into the time stream of each observation to measure the response of the model source to filtering.

2.3 Maps and source detection

We present the 450 µm signal-to-noise ratio map of the COSMOS/CANDELS field in Fig. 1. For comparison, we also show a Herschel-SPIRE 500 µm map of the same region to illustrate the gain in resolution that JCMT/SCUBA-2 offers at similar wavelengths.5 The 450 µm map has a radially varying sensitivity, which is nearly uniform over the central 3 arcmin (the nominal mapping area) and smoothly increases in the radial direction as the effective exposure time decreases for pixels at the edge of the scan pattern, which have fewer bolometers contributing to the accumulated exposure. The total area of the map considered for source

3 Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey, http://candels.ucolick.org/
4 http://www.jach.hawaii.edu/JCMT/continuum/
5 The Herschel map was made from the level 2.5 processed data products downloaded from the public Herschel Science Archive. The data were co-added with sky coverage used as an estimator for image noise level, and re-binned into the SCUBA-2 image reference frame, using the nearest neighbour sampling. The 1σ noise level of this SPIRE map (including confusion) is 6.2 mJy beam$^{-1}$.

S2CLS: 450 µm number counts and the CIB 55

---

Downloaded from http://mnras.oxfordjournals.org/ at Durham University Library on November 20, 2013
Figure 1. Left: SCUBA-2 450 µm signal-to-noise ratio map of the COSMOS/CANDELS field. The map has been scaled to emphasize the visibility of 60 sources detected at >3.75σ significance (circled). The grey contours show the variation in the noise level, and are at σ450 = 2, 3, 4, 5 mJy beam−1 (the solid angle bounded by the σ450 = 5 mJy beam−1 contour is Ω ≈ 140 arcmin2). Right: Herschel-SPIRE 500 µm image of the same region, from the Herschel Multi-tiered Extragalactic Survey (HerMES) survey (Oliver et al. 2012). This map has been slightly smoothed with a Gaussian kernel to improve presentation. We show the limiting σ450 = 5 mJy beam−1 contour used for 450 µm detection in the SCUBA-2 map and the position of the same galaxies in the left-hand panel. This illustrates the ability of SCUBA-2 to push below the Herschel confusion limit at similar wavelengths, resolving confused emission into individual galaxies.

To identify extragalactic point sources, we search for pixels in the (beam convolved) signal-to-noise ratio map with values >σthresh. If a peak is found, we record the peak-pixel sky coordinate, flux density and noise, mask-out a circular region equivalent to ≃1.5 times the size of the 8 arcsec beam at 450 µm, reduce Σthresh by a small amount and then repeat the search. The floor value, below which we no longer trust the reality of ‘detections’ is chosen to be the signal-to-noise level at which the contamination rate due to false detections (expected from pure Gaussian noise) exceeds 5 per cent, corresponding to a significance of σ ≈ 3.75. We detect 60 discrete point sources in this way, and these are identified in Fig. 1. Note that the map is far from confused, with an average source density equivalent to 6 × 10−3 beam−1. We project that the confusion limit is at ∼1 mJy beam−1.

Completeness is estimated by injecting a noise model with artificial point sources. To create maps with no astronomical sources but approximately the same noise properties of the real map, we generate jackknife realizations of the map where, in each fake map, a random half of individual scans have their signal inverted before co-addition (e.g. Weiss et al. 2009). Fig. 2 shows the equivalent histogram of signal-to-noise ratio values in the jackknife map, which demonstrates the clean removal of astronomical sources, and the similarity with pure Gaussian noise. The recovery rate of sources as a function of input flux and local noise gives the completeness function: 105 fake sources in batches of 10 are inserted into the jackknife map, where each source selected from a uniform flux distribution 1 < (S450/mJy) < 40. The two-dimensional completeness function is shown in Fig. 3.

Figure 2. Histogram of values in the SCUBA-2 450 µm signal-to-noise ratio map (Fig. 1), indicating the characteristic positive tail due to the presence of real astronomical sources. The solid line is a Gaussian centred at zero with a width of σ = 1, and the darker shaded histogram shows the histogram of pixel values in a map constructed by inverting a random 50 percent of the input scans; we use this for simulations of completeness, described in Section 2.3. Our detection limit is chosen to be σ = 3.75, which yields a reasonably complete and reliable catalogue (see Section 2.3). Note that the ‘real’ map noise distribution is slightly wider than expected for pure Gaussian noise; this is due to slight ‘ringing’ around bright sources after convolution with the beam.
Figure 3. Completeness of the 450 μm catalogue as a function of local noise and input flux based on input-and-recovery simulations using jackknife realizations of the map noise. Modelling the completeness as a two-dimensional function is required due to the radially varying sensitivity in the map (Fig. 1). The same simulations allow us to estimate the difference between true (input) flux and recovered (i.e. observed) flux densities across the same parameter space, and we use this information to correct the number counts accordingly.

Table 1. Number counts of 450-μm-selected galaxies. N indicates the raw number of galaxies in each bin (δS450 = 5 mJy), and the completeness (C) and de-boosting (B) corrections represent the mean corrections for galaxies in each bin (note that each galaxy is de-boosted individually, with the correction increasing for lower flux densities). Uncertainties in the differential counts are the 1σ confidence range assuming Poisson statistics ( Gehrels 1986).

| S450 (mJy) | N   | dN/dS (mJy⁻¹ deg⁻²) | N(≥S) a (deg⁻²) | ⟨C⟩ b | ⟨B⟩ c |
|------------|-----|----------------------|-----------------|------|------|
| 8.0        | 41  | 343.0±62.6           | 2313.4±599.7    | 1.6  | 1.1  |
| 13.0       | 13  | 88.5±32.3            | 598.5±172.4     | 1.1  | 1.1  |
| 18.0       | 4   | 20.8±16.8            | 155.9±44.7      | 1.0  | 1.0  |
| 23.0       | 2   | 10.4±14.2            | 52.6±31.0       | 1.0  | 1.0  |

a S corresponds to the lower edge of the bin, i.e. (S450 = 2.5) mJy;
b Average completeness correction applied;
c Average flux de-boosting correction applied.

In addition to the completeness correction, this technique allows us to estimate the noise-dependent flux boosting that occurs for sources with true fluxes close to the noise limit of the map, and so we can construct an equivalent ‘surface’ in the noise–(measured) flux plane that can be used to de-boost the fluxes measured for point sources in the real map (Table 1). The typical de-boosting correction is B < 10 per cent. Finally, the source detection algorithm is applied to each of the jackknife maps with no fake sources injected in order to evaluate the false positive rate, which we find to be 5 per cent, in agreement with the false detection rate expected for a map of this size assuming fluctuations from pure Gaussian noise.

A test for any bias in the recovery and correction of the source counts was performed in the following way. We populated the jackknife maps with a model source count model (Béthermin et al. 2012b) down to a flux limit of S450 = 0.01 mJy. Sources were then extracted in exactly the same manner as the real data and completeness and flux boosting corrected as described above and then compared to the input distribution. This procedure was repeated 100 times and the average recovered source counts compared to the input model. The recovered differential and cumulative number counts were found to be consistent with the input number count realizations, indicating that our source detection and completeness corrections are not significantly biased.

3 ANALYSIS

3.1 Number counts of 450 μm emitters

In Table 1 and Fig. 4, we present the number counts at 450 μm, corrected for flux boosting and incompleteness. The differential counts are well described by a Schechter function:

\[
\frac{dN}{dS} = \left( \frac{N'}{S} \right) \left( \frac{S}{S'} \right)^{-\alpha} \exp \left( \frac{N'}{S} \right),
\]

with \( S' = 10 \text{ mJy} \) (fixed at a well-measured part of the flux distribution), \( N' = (490 \pm 104) \text{ deg}^{-2} \) and \( \alpha = 3.0 \pm 0.7 \). We choose to fit a Schechter function rather than a power law (or broken power law), since it is more physically motivated. While it may be that an extrapolation to a power law, fitted to the new 450 μm data alone, would better model the counts at a similar wavelength at flux densities above 20 mJy (at the bright end the number counts from this survey are complemented by the equivalent measurements from Herschel surveys, which survey wider areas at 500 μm to shallower depths, e.g. Clements et al. 2010; Negrello et al. 2010), it is known that in this flux regime the observed counts are significantly affected (boosted) by gravitational lensing (Negrello et al. 2010). In this case, the raw Schechter form naturally fails to model the bright-end counts, but is likely to be a more appropriate model of the submillimetre counts in the observed flux range, and – perhaps more importantly for CIB studies – when extrapolating the number counts to faint flux densities.

We compare our results to two Herschel surveys; HerMES, which has obtained confusion limited maps reaching a detection limit of \( S_{500} \approx 20 \text{ mJy} \) (Oliver et al. 2012) and the Herschel-ATLAS survey, which has mapped several hundreds of square degrees at a shallower depth (Eales et al. 2010). The wider Herschel surveys detect rarer (bright local and distant lensed) galaxies that the SCUBA-2 map is too small to probe. As Fig. 4 shows, our 450 μm counts are in excellent agreement at \( \approx 20 \text{ mJy} \) where the Herschel and SCUBA-2 CLS survey flux distributions meet. Below Herschel’s confusion limit the 500 μm galaxy number counts have been inferred statistically, by both stacking (Béthermin et al. 2012b) and pixel fluctuation analyses (Glenn et al. 2010), again indicating consistency with the directly measured 450 μm number counts in approximately the same flux regime.

Recently, Chen et al. (2013) presented SCUBA-2 450 μm observations of SMGs in the field of the lensing cluster A 370. The benefit of observing a lensing cluster is – provided a lens model is known – the ability to probe further down the luminosity function than would otherwise be possible for the same flux limit, with faint background sources boosted by the cluster potential. We compare the ‘de lensed’ counts of 450 μm emitters derived from 12 galaxies in the field of A 370 in Fig. 4, indicating broad agreement with our blank-field counts within the errors in the same flux range. After delensing, Chen et al. (2013) are able to probe slightly fainter than our catalogue, and the number counts at the 4.5 mJy level are
also consistent with an extrapolation of our best-fitting Schechter function to the same limit.

3.2 Resolving the 450 µm background light

What fraction of the CIB at 450 µm have we resolved into galaxies? The integrated flux density of point sources detected at 450 µm (corrected for completeness) is $I_{\nu}(450\mu m) = (7.4 \pm 0.7) \times 10^{-5}$ MJy sr$^{-1}$. The absolute intensity of the CIB at 450 µm measured by COBE–Far Infrared Absolute Spectrophotometer (FIRAS) is $I_{\nu}(450\mu m) = 0.47 \pm 0.19$ MJy sr$^{-1}$, thus we have directly resolved 16 ± 7 per cent of the CIB at 450 µm (the uncertainty is dominated by the COBE–FIRAS measurement; Fixsen et al. 1998). For comparison, the deepest Herschel surveys have directly resolved 5–6 per cent of the CIB at 500 µm (Oliver et al. 2010; Béthermin et al. 2012a). We show the integrated brightness of the 450 µm emitters, relative to the absolute intensity of the CIB in Fig. 4.

To measure the contribution to the CIB at 450 µm by galaxies not formally detected in the SCUBA-2 map, but which are known to be infrared-bright galaxies, we stack the map at the position of 1600 galaxies selected from a catalogue generated from the Spitzer-COSMOS Multiband Imaging Photometer (MIPS) 24 µm image of the same region (Sanders et al. 2007). First, we remove point sources from the 450 µm map, using a point spread function (PSF) constructed by averaging the two-dimensional profiles of sources detected at $>7\sigma$. This PSF was then normalized to the flux of each individual source in our catalogue, and subtracted from the map. This yields a residual map, where the only flux (in addition to that of noise) is contributed by sources not in our catalogue. The 450 µm is then stacked at the position of the 24 µm sources, averaging the flux with a weight equivalent to the inverse of the variance of the map at each position.

The average 450 µm flux density of 24 µm sources with mean 24 µm flux $\langle S_{24} \rangle = 0.19$ mJy is $\langle S_{450} \rangle = 2.2 \pm 0.4$ mJy. The resulting contribution to the 450 µm background is 0.20 ± 0.04 MJy sr$^{-1}$ (the uncertainty is $\sigma/\sqrt{N}$, with $\sigma$ the standard deviation in the stack and $N$ the sample size). A simple simulation was performed to test whether the stacking methodology described above produces unbiased estimates of the submillimetre flux. The residual flux map was inverted (by multiplying by $-1$) and simulated sources were inserted using the derived PSF as a model, with the input fluxes of the fake sources set to $S_{450} = 10S_{24}$ up to a maximum of $S_{450} = 5$ mJy. The positions were set to the 24 µm catalogue positions, rotated 90 degrees about the map centre, thus preserving clustering information. The stacking procedure was then repeated as for the real catalogue. The mean input flux was $S_{450} = 1.8$ mJy per source, and the recovered stacked flux was $S_{450} = 1.0 \pm 0.5$ mJy. The recovered flux is slightly low compared to the input flux at the 1.5σ level; however, this does not affect our conclusions, given the uncertainties in the 450 µm flux calibration and the absolute measured value of the CIB at 450 µm.

Excluding those detected as bright point sources, the 24-µm-selected galaxies contribute $(2.0 \pm 0.4) \times 10^{-11}$ MJy sr$^{-1}$ or $42 \pm 19$ percent of the CIB at 450 µm. Therefore, in addition to the directly detected sources, in total we can account for 58 ± 20 percent of the CIB at 450 µm. Note that our stacked value is in good agreement with the background derived from a stack of 24 µm emitters in Herschel 500 µm images ($2.6^{+0.4}_{-0.6}) \times 10^{-11}$ MJy sr$^{-1}$;
Béthermin et al. 2012a), and is also reasonably consistent with the intensity expected from an extrapolation of a Schechter function fit to the directly measured number counts (0.14 MJy sr⁻¹; Fig. 4).

4 DISCUSSION

We compare our results to the phenomenological model of Béthermin et al. (2012b), who use a ‘backwards evolution’ parametrization of the infrared luminosity density (as traced by dusty star-forming galaxies; see also Lagache et al. 2004). The Béthermin et al. (2012b) model assumes that the star formation modes of galaxies can be either described as ‘main sequence’ [i.e. star formation rate (SFR) scales with stellar mass] or ‘starburst’, with spectral energy distributions defined by the latest stellar synthesis template libraries. The evolution of the luminosity functions of these two populations integrated over cosmic history provides good fits to the observed number counts of galaxies at 24, 70, 100, 160, 250, 350, 500, 850, 1100 µm and 1.4 GHz (as well as integrated observables such as the evolution of the volume-averaged SFR and CIB). Here, we confirm that the number counts of 450 µm emitters predicted by the model is also in good agreement with the measured 450 µm number counts in the flux range probed by our SCUBA-2 survey.

We also compare the measured counts to the GALFORM semi-analytic model of galaxy formation (Cole et al. 2000; Baugh et al. 2005; Lacey et al. 2008; Almeida et al. 2011). This prescription predicts the formation and evolution of galaxies within the Λ cold dark matter model of structure formation, and includes the key physics of the galaxy formation (and evolution) process: radiative cooling of gas within the dark matter haloes, quiescent (by which we mean non-burst driven) star formation in the resultant discs, mergers, chemical enrichment of the stellar populations and intergalactic medium and feedback from supernovae. As Fig. 4 shows, the numerical model slightly overpredicts the abundance of 450 µm emitters in the flux range probed. Nevertheless, the reasonable agreement between the shape of the counts predicted by GALFORM and the data is encouraging for models of galaxy formation that aim to reproduce the full range of emission processes of galaxies at long wavelengths.

The 8 arcsec resolution of the 450 µm SCUBA-2 map allows us to accurately identify the optical/near-infrared counterparts of the SMGs, and we have identified the most likely counterpart to the majority (54/60) of 450 µm-selected samples, which have typical redshifts of ⟨z⟩ = 1.3, and the vast majority of the 450-µm-selected SMGs lie at z< 3. For comparison, the average redshift of SMGs selected at 850 µm is z ≈ 2.2 (Wardlow et al. 2010), indicating the efficacy at which the 450 µm selection samples a population of SMGs at lower redshift and therefore an important complement to any census of the dusty Universe. We compare the shape of the redshift distribution to the models of Béthermin et al. (2012b) and Lacey et al. (2008) shown in Fig. 4 for galaxies with S 160 > 5 mJy (we have area-normalized both model distributions, since the observed redshift distribution contains no completeness correction). The average redshift and shape of both model distributions is in good agreement with observations, suggesting that – at this flux limit – there is little contribution from galaxies at z> 3.

The 8 arcsec resolution of the 450 µm SCUBA-2 map allows us to accurately identify the optical/near-infrared counterparts of the SMGs, and we have identified the most likely counterpart to the majority (54/60) of 450 µm sources in our sample (Roseboom et al., in preparation). The wealth of legacy data available in the COSMOS field then provides the means to estimate the redshift distribution of the population. We have used 13 bands of optical/near-infrared photometry, including Canada–France–Hawaii Telescope ugri, Subaru SuprimeCam z’, Visible and Infrared Survey Telescope for Astronomy (VISTA) YJHK, HST F125W and F160W and Spitzer Infrared Array Camera (IRAC) [3.6] and [4.5] to evaluate the photometric redshifts of all the identified galaxies (the typical σ uncertainty based on the confidence level of the template fit is δz ≈ 0.16). The redshift distribution is shown in Fig. 5, indicating that the majority of our sample lie at z< 3, with a mean redshift of ⟨z⟩ = 1.3 (a full analysis of the source identification and redshift distribution is to be presented in Roseboom et al., in preparation). This is a clear indication that the 450 µm selection is probing a lower redshift population than previous 850-µm-selected samples, which have typical redshifts of ⟨z⟩ = 2.2 (e.g. Chapman et al. 2005; Wardlow et al. 2010). The shape of the redshift distributions predicted both by the phenomenological model and numerical model described above (for galaxies at the same flux limit) are also in good agreement with the measured distribution; both models predict little contribution from galaxies at z> 3 (although a high-redshift ‘tail’ is present in both models).

Assuming the directly detected sources representing 16±7 per cent of the CIB at 450 µm are star-forming galaxies at ⟨z⟩ = 1.3, then their total (rest-frame 8–1000 µm) luminosities are in the ultraluminous class, LIR ≈ 1.1 × 10^{12} L⊙ (Chary & Elbaz 2001). If the galaxies contributing to the 24 µm stack described in Section 3.3 lie in the same redshift range as the directly detected galaxies, then the majority (60 per cent) of the CIB at 450 µm is emitted by galaxies with LIR > 3.6 × 10^{11} L⊙. This is broadly consistent with the picture that at z ≈ 1, the SFR budget of the Universe is dominated by galaxies in the luminous infrared galaxy (LIRG) class, with SFRs of the order of 10 M⊙ yr⁻¹ (Dole et al. 2006; Rodighiero et al. 2010; Magnelli et al. 2011).

An extrapolation of the Schechter function fit to the directly measured number counts (which agrees well with the background at S 850 ≈ 2 mJy, derived from the stack of 24 µm sources), implies that 100 per cent of the CIB at 450 µm should be recovered at 0.1 < S 850 < 1.4 mJy (the range accounting for the 1σ uncertainty of the absolute measured background; Fixsen et al. 1998), close to the SCUBA-2 confusion limit. If the galaxies responsible for this emission are at similar redshifts to the current 450 µm sample (but below the sensitivity of the map and not contributing to the 24 µm stack), then the majority of the remaining ≈40 per cent of the CIB at 450 µm is likely to be emitted by galaxies with LIR < 1.3 × 10^{11} L⊙, implying galaxies SFRs of a few tens of Solar masses.
per year. However, we cannot as yet rule out what fraction of the
remaining CIB light might be emitted by faint 450 µm emitters at
higher redshifts; note that a galaxy with $S_{150} \approx 2$ mJy at $z > 2$
in the ultraluminous class, with a typical luminosity of $L_{IR} > 5.5 \times 10^{11} \, L_\odot$ (Chary & Elbaz
2001), again indicating the importance of LIRG-class galaxies in the
cosmic infrared budget. Characterizing the high-redshift tail of the
450 µm population is an important next step.

5 SUMMARY
The SCUBA-2 camera on the 15 m JCMT represents the state-of-the-art in panoramic submillimetre imaging, and has recently begun
scientific observations in earnest. In this paper, we have presented
results from the first deep, blank-field cosmological map at 450 µm
($\sigma_{150} = 1.3$ mJy); part of the S2CLS, the largest of the seven
JCMT Legacy Surveys. Using a 450 µm map of the well-studied
eextragalactic COSMOS/CANDELS field, we have

(i) made the first unbiased, blank-field determination of the
number counts of galaxies at 450 µm, at a flux density limit of $S_{150} > 5$
mJy. This probes below the confusion limit of Herschel, comple-
menting the number counts measured at fluxes above 20 mJy over
wider areas in major Herschel submillimetre surveys;

(ii) measured the contribution of these galaxies to the CIB at
450 µm: we resolve 16 percent of the CIB into individual galaxies.
The ability of SCUBA-2 to ‘pin-point’ the galaxies responsible
for the emission of the CIB is a critical step in understanding the
properties of the galaxies that are forming the majority of stars in
the Universe at this epoch;

(iii) an additional ≈ 40 percent of the CIB can be recovered in the
SCUBA-2 map by stacking Spitzer MIPS-detected 24 µm emitters.
Using this analysis we estimate that the majority (≈60 percent)
of the CIB at 450 µm is emitted by galaxies with $S_{150} > 2$ mJy;

(iv) a preliminary analysis of the redshift distribution of the
450 µm emitters (based on high-quality photometric redshifts avail-
able for this field) imply that the typical redshift of galaxies with
$S_{150} > 5$ mJy is $z = 1.3$, with the majority lying at $z < 3$. The
typical luminosity of galaxies in our sample is estimated to be in
the ultraluminous class, with $L_{IR} > 10^{12} \, L_\odot$. If the galaxies con-
tributing to the statistical stack of 24 µm emitters described above are
at a similar redshift, then we project that the majority of the CIB at 450 µm is emitted by ‘LIRG’ class galaxies with $L_{IR} > 1.3 \times 10^{11} \, L_\odot$.

ACKNOWLEDGEMENTS
JEG is supported by a Banting Fellowship, administered by NSERC.
JSD acknowledges the support of the European Research Council
via the award of an Advanced Grant, and the support of the Royal
Society via a Wolfson Research Merit award. MM and IGR ac-
knowledge the support of STFC. The authors thank M. Béthermin for
providing data on the 500 µm stacking and parametric model, and
J. Dempsey for advice on the SCUBA-2 calibration. It is also a
pleasure to thank the JCMT telescope operators J. Hoge, J. Wouter-
loot and W. Montomieu, without whom these observations would
not be possible. The JCMT is operated by the Joint Astronomy
Centre on behalf of the Science and Technology Facilities Council
of the United Kingdom, the Netherlands Organisation for Scienti-
fic Research and the National Research Council of Canada. Ad-
ditional funds for the construction of SCUBA-2 were provided by
the Canada Foundation for Innovation. Herschel is an ESA space
observatory with science instruments provided by European-led
Principal Investigator consortia and with important participation
from NASA. This work is based in part on observations made with
the Spitzer Space Telescope, which is operated by the Jet Propulsion
Laboratory, California Institute of Technology under a contract with
NASA.
