ABSTRACT

XMMU J004243.6+412519 is a transient X-ray source in M31, first discovered in 2012 January 15. Different approaches to fitting the brightest follow-up observation gave luminosities 1.3–2.5 × 10^39 erg s^{-1}, making it the second ultraluminous X-ray source (ULX) in M31, with a probable black hole accretor. These different models represent different scenarios for the corona: optically thick and compact, or optically thin and extended. We obtained Chandra ACIS and Hubble Space Telescope Advanced Camera for Surveys observations of this object as part of our transient monitoring program, and also observed it serendipitously in a 120 ks XMM-Newton observation. We identify an optical counterpart at J2000 position 00:42:43.70 +41:25:18.54; its F435W (~B band) magnitude was 25.97 ± 0.03 in the 2012 March 7 observation, and >28.4 at the 4σ level during the 2012 September 7 observation, indicating a low-mass donor. We created two alternative light curves, using different corona scenarios, finding linear decay for the compact corona and exponential decay for the extended corona; linear decay implies a disk that is <5 mag brighter than we observed. We therefore favor the extended corona scenario, but caution that there is no statistical preference for this model in the X-ray spectra alone. Using two empirical relations between the X-ray to optical ratio and the orbital period, we estimate a period of ~9–30 hr; this period is consistent with that of the first ULX in M31 (18±3 hr).

Key words: black hole physics – X-rays: binaries – X-rays: general

Online-only material: color figures

1. INTRODUCTION

Ultraluminous X-ray sources (ULXs) are point sources with X-ray luminosities exceeding the Eddington limit for a 10 M☉ black hole (≈1.3 × 10^39 erg s^{-1}) that are unrelated to galaxy nuclei (see, e.g., Roberts 2007; Feng & Soria 2011 for reviews). ULXs are often associated with regions of high star formation such as spiral arms of galaxies, and therefore many are likely to be related to high-mass X-ray binaries (HMXBs; see, e.g., Mapelli et al. 2010; Mineo et al. 2012, and references therein). Some ULXs may contain intermediate mass black holes (ESO 243-49 HLX-1 being a strong candidate; Farrell et al. 2009). Other ULXs may harbor stellar mass black holes, exhibiting true super-Eddington accretion (see, e.g., Gladstone et al. 2009; Barnard 2010), or apparent super-Eddington luminosities due to beaming (e.g., King et al. 2001). Since ULXs are simply defined by their observed luminosities, their membership is likely to include a wide range of diverse systems.

High-quality ULX spectra are often described by a two-component emission model, consisting of a disk blackbody component and a component such as comptt that represents inverse-Comptonization of cool photons on hot electrons in an accretion disk corona. Some people expect the temperature of the seed photons (T_0) to equal the inner disk temperature (kT_in), assuming that the corona is compact and so only sees the inner disk (see, e.g., Roberts et al. 2005; Gonçalves & Soria 2006). However, many high-quality ULX spectra reject models where T_0 = kT_in (Gladstone et al. 2009); instead, successful models fall into one of two types.

The first type results in cool, optically thick coronae where T_0 > kT_in; Gladstone et al. (2009) proposed that these spectra represent a separate “ultraluminous state” where an opaque corona hides the inner disk from view, meaning that the measured value for kT_in comes from further out in the disk, outside the corona. ULXs fitted this way tend to have a soft excess, and a rollover in the spectrum above 3 keV (Gladstone et al. 2009). This state is distinct from the spectral states observed in Galactic X-ray binaries (XBs), where the optical depth is ≤1. The corona must be compact, so that we still see the inner disk in X-rays; this is also different from Galactic XBs, where corona estimates range over ~20,000–700,000 km for high inclination systems (Church & Bahcall-Isaak-Church 2004), while Chandra grating spectroscopy of Cygnus X-2 suggests a corona ~100,000 km (Shulz et al. 2009).

The second type results in optically thin coronae with T_0 < kT_in and is also well described by a disk blackbody + power-law model for some sources; these spectra represent an extended corona (Barnard 2010), and may be related to the steep power-law (SPL) state observed in canonical black hole binaries (see, e.g., Remillard & McClintock 2006). The electron temperature determines whether or not the Comptonized component is well described by a power law; if the electron temperature is too close to (or within) the observed energy band, then the power law fails and more specialized models of Comptonization are required (e.g., comptt). These coronae are optically thin, meaning that we are able to see a portion of the disk emission even though the disk is extended. Extended corona allow super-Eddington emission while keeping the local accretion rate sub-Eddington.

When disk blackbody + power-law models are applied, the power-law component sometimes dominates the low energy emission; this has regarded as unphysical by some (see, e.g., Roberts et al. 2005; Gonçalves & Soria 2006). This led Steiner et al. (2009) to develop the simple model of Comptonization for XSPEC v.12 that results in a single, Comptonized emission component. Barnard (2010) modeled XMM-Newton emission spectra of three ULXs in NGC 253 (plus the
dynamically confirmed BH + Wolf–Rayet binary IC10 X-1) with two-component models and convolution models. The convolution model was rejected for NGC 253 ULX3 and IC10 X-1 (and the luminosity for IC10 X-1 was well sub-Eddington). NGC 253 ULX1 and NGC 253 ULX2 preferred the two-component model over the convolution model (with lower χ^2 for the same number of degrees of freedom). We infer from these results that the soft excess is real, and favor an extended corona (i.e., T_0 < kT_e). We present a possible explanation for the soft excess in the discussion.

XMMU J004243.6+412519 is a transient X-ray source in M31, identified for the first time in a 2012 January 15 XMM-Newton observation, hereafter observation X1 (Henze et al. 2012d); its luminosity was found to be ∼2 × 10^{38} erg s⁻¹. Henze et al. (2012a) observed the source again twice more with XMM-Newton (observations X2–X3); the highest observed luminosity (in X3) was 2.5 × 10^{39} erg s⁻¹, assuming a two-component emission model consisting of a power law with photon index Γ = 2.7 ± 0.1, and a disk blackbody with inner disk temperature kT_in = 0.79 ± 0.05 keV, suffering line-of-sight absorption equivalent to 6.2 ± 0.5 × 10^{21} H atoms cm⁻². This luminosity is a factor ∼2 higher than the Eddington limit for a standard 10 M_☉ black hole, hence Henze et al. (2012a) labeled it a ULX. Since this is the second ULX in M31, we will refer to this source as M31 ULX2.

Henze et al. (2012b) followed up the XMM-Newton observations of M31 ULX2 with five Swift observations (S1–S5) over 2012 February 19—March 4 that were consistent with constant intensity; they combined the spectra, and found the summed spectrum to be well described by either a pure 0.88 ± 0.04 keV disk blackbody or a 0.9 ± 0.3 keV disk blackbody + power law with Γ fixed to 2.7. A further 2012 May 24 Swift observation (S6) resulted in a spectrum that was well described by a 0.66^{+0.07}_{−0.06} keV disk blackbody, absorbed by 4.0^{+1.4}_{−1.1} × 10^{21} atoms cm⁻² (Henze et al. 2012c).

Middleton et al. (2012) discovered strong variable radio emission associated with the X-ray source during outburst, and found it likely that the radio source was a jet powered by near-Eddington accretion onto a stellar mass black hole.

They also carefully modeled the X-ray spectra from X1–X3, and found that an emission model consisting of a disk blackbody (diskbb) + Comptonization model (comptt) was preferred for X2 and X3 over the disk blackbody + power-law model used by Henze et al. (2012b); however, they do not discuss this in detail. For their diskbb + comptt models, kT_in ∼ 0.5 keV, T_0 ∼ 1.2 keV, and the optical depth of the corona was ∼11; they did not give the electron temperature. The resulting 0.3–10 keV luminosities were considerably lower than those obtained by Henze et al. (2012b): 9.8 ± 0.2 × 10^{38} and 1.26 ± 0.02 × 10^{39} erg s⁻¹ for X2 and X3, respectively. Middleton et al. (2012) present spectra for M31 ULX2 at various stages of its spectral evolution.

The Middleton et al. (2012) emission model represents the T_0 > kT_in family of models, while the Henze et al. (2012a) model represents the T_0 < kT_in model family. We will therefore consider the luminosity solutions for X2 and X3 from Henze et al. (2012b), as well as those of Middleton et al. (2012).

Two types ofXBs exhibit transient behavior. Low-mass XBs may be transient X-ray sources due to instabilities in their accretion disks; the disk has two stable phases (hot and cold), and an unstable intermediate phase—matter accumulates in the disk in the cold phase, and is rapidly dumped onto the compact object in the hot phase (see, e.g., Lasota 2001). However, the X-rays produced by accretion from the hot disk prevent the disk from cooling; the X-ray luminosity decays exponentially if the whole disk is ionized, and linearly if only part of the disk is ionized (King & Ritter 1998). Meanwhile HMXBs with large eccentricities may be transient if mass transfer is only possible near periastron, or if Be class donor stars experience ejection events (see, e.g., Stella et al. 1986).

We have been monitoring the central region of M31 for the last ∼13 years with Chandra, averaging ∼1 observation per month, looking for X-ray transients. Promising examples are followed up with two Hubble Space Telescope (HST) Advanced Camera for Surveys (ACS) observations, the first is taken a few weeks after outburst, and the second observation is taken ∼6 months later; this allows us to identify the counterpart via difference imaging (see, e.g., Barnard et al. 2012a, and references therein).

van Paradijs & McClintock (1994) found an empirical relation between the ratio of X-ray and optical luminosities of Galactic XBs and their orbital periods, suggestive that the optical emission is dominated by reprocessed X-rays in the disk; this relation appears to be independent of inclination. Their chosen X-ray band was 2–10 keV. For an irradiated accretion disk with radius a, X-ray luminosity L_X, optical luminosity L_opt, and temperature T, T_k ∝ L_X/a^2, while the surface brightness of the disk, S, ∝ T^2 for typical XBs (van Paradijs & McClintock 1994). Since L_opt ∝ S ∝ a^2, L_X ∝ L_X/a^2; also a ∝ P_{orb}^{2/3}, where P_{orb} is the orbital period.

van Paradijs & McClintock (1994) defined Σ = (L_X/L_{edd})^{1/2} (P_{orb}/1 hr)^{1/3}, choosing a L_{edd} = 2.5 × 10^{38} erg s⁻¹ as a normalizing constant, and found

M_X = 1.57(±0.24) – 2.27(±0.32) log Σ. (1)

However, van Paradijs & McClintock (1994) sampled a mixture of neutron star and black hole binaries, in various spectral states. A cleaner sample was obtained by A. Moss et al. (2013, in preparation), who used only black hole transients at the peaks of their outburst, and found

M_X = 0.84(±0.30) – 2.36(±0.30) log Σ. (2)

We note that these two relations only differ significantly in normalization, caused by black hole XBs having larger disks than neutron star binaries with the same period. We have period estimates for 12 M31 transients observed by Chandra and HST (Barnard et al. 2012a).

We used our first Chandra observation of M31 ULX2 (2012 February 19, C1) to refine its X-ray position to 00:42:43.683 ±24 in R.A. and 00:20 in decl. (Barnard et al. 2012b). We then triggered two HST/ACS observations, using the F435W filter that approximates the B band.

In this work, we present analysis of our Chandra and HST observations of M31 ULX2 (C1–C9 and H1–H2, respectively), as well as a serendipitous observation in a 120 ks XMM-Newton observation (PI: R. Barnard); we refer to this observation as X4. We also re-analyzed the Swift observations S1–S6, in order to obtain uncertainties on their fluxes; X1–X3 were not available to the public. We also give a range of orbital periods estimated for the system.

2. OBSERVATIONS AND DATA REDUCTION

We observed M31 ULX2 nine times with Chandra ACIS over 2012 February–September (C1–C9); unfortunately, M31
was unobservable for much of March and April, resulting in a 
\( \sim 100 \) day delay between C1 and C2. Our two HST observations 
were made on 2012 March 7 (H1) and September 7 (H2). We 
serendipitously observed M31 ULX2 with XMM-Newton for 
120 ks on 2012 June 26 (X4, PI: R. Barnard).

2.1. Optical Analysis

All optical analysis was performed with pc-iraf Revision 
2.14.1, except where noted. Each HST observation included four 
flat-fielded (FLT) images and one drizzled (DRZ) image. The 
flat-fielded images are corrected for instrumental effects, but not
background subtracted; the total number of counts in each pixel 
is given. The native ACS resolution is comparable to the FWHM of 
the point spread function (PSF) (Fruchter et al. 2009). The 
drizzled image combines the flat-fielded images, removes any 
cosmic rays, and subtracts the sky background; it is normalized 
to give the number of counts per second per pixel. We used the 
DRZ images from H1 and H2 to create a difference image; how-
ever, we mainly used the FLT images for our aperture photom-
etry because the software used (DAOPHOT) prefers images that 
include the sky background and measure brightness in counts.

2.1.1. Creating a Difference Image

We reprojected the H2 DRZ image into the coordinates of the 
H1 DRZ image, to produce an accurate difference image. To 
do this, we first registered the H2 image to the H1 image with 
ccmap, using unsaturated stars that were close to the target; this 
maximized the accuracy of the registration at the position of 
the target. Then, we used the iraf task wregister to make the 
pixel orientation of the H2 image match that of the H1 image. We 
registered the H2 image to the H1 image before mapping to 
reduce the noise during image subtraction. The difference image 
was produced by subtracting H2 from H1 using the ftools task 
farith.

2.1.2. Measuring the Optical Counterpart

For our first HST observation (H1), we used the daoPhot 
package released with iraf to obtain the net source counts in 
the FLT images, for a total of \( C_{\text{tot}} \) counts over \( T \) seconds. In 
particular, we used daofind to obtain the number of source 
counts from radial profile fitting. We converted this to Vega B 
magnitude via

\[
B \simeq -2.5 \log \left( \frac{C_{\text{tot}}}{T} \right) + \text{ZP},
\]

having obtained the zero point (ZP = 25.77) from the ACS 
Zero Point calculator\(^3\); we see from Sirianni et al. (2005, 
Equation (12) and Table 18) that the conversion from F435W 
counts to \( B \) magnitude is within \( 3 \sigma \) of our ZP for \( B - V = -0.09 
\) (assuming a typical disk spectrum; Liu et al. 2001). We 
can convert from \( B \) magnitude to \( M_V \) via

\[
M_V = B + 0.09 - N_H \times (1 + 1/3) \times 1.8 \times 10^{21} - 24.47,
\]

where \( N_H \) is the line-of-sight absorption; this accounts for the 
difference in \( B \) and \( V \) magnitudes of a typical accretion disk, a 
relationship between \( B \)-band extinction and measured line-of-
sight absorption toward the object, and the distance to M31 (see 
Barnard et al. 2012a, and references therein).

For the second observation (H2), we examined each FLT 
image and found the total number of background counts in 
a circular region with 3 pixel radius at the position of the 
counterpart; this corresponds to \( \sim 3 \) times the FWHM width 
of the PSF. We obtained the \( 4 \sigma B \) magnitude upper limit from 
\( 4 (C_{\text{tot}})^{0.5} / T \).

2.2. X-Ray Analysis

We extracted spectra from our X-ray observations of M31 
ULX2 using the appropriate mission-specific software suites: 
CIAO v.4.4 for C1–C9, HEASoft v6.13 for S1–S6, and 
XMM-Newton SAS v.12.0.1 for X4. We used the CALDB 
version distributed with CIAO. Spectral analysis was performed 
with XSPEC v12.7.1b.

2.2.1. Chandra Analysis

For each of our Chandra ACIS observations (C1–C9), we 
extracted source and background 0.3–7.0 keV spectra from 
circular regions with \( 20'' \) radii; the high off-axis angle meant 
that the PSF was considerably larger than for an on-axis point 
source. We then created a response matrix using mkacisrmf, 
and obtained an ancillary response file from mkarf. The source 
spectra were grouped to give a minimum of 20 counts per bin 
using grppha.

2.2.2. Swift Analysis

Following the recommended procedure, we extracted source 
spectra from a circular region with 20 pixel (47'') radius, using 
xselect v2.4b. The background spectra were accumulated from 
a nearby circular region with 40 pixel (94'') radius. We then 
produced ancillary response files using xrtmkarf, using the 
included exposure map to account for variations in effective 
area over the observation. Swift response files are not generated 
on the fly; instead, the correct response is found by using the 
quzciF tool, and copied into the working directory. Spectral 
channels 0–29 were labeled bad, and the spectra were grouped 
to give at least 20 counts per bin using grppha.

2.2.3. XMM-Newton Analysis

Due to the high intensity of M31 ULX2, we only used data 
from the pn instrument. XMM-Newton observations often 
experience intervals of greatly increased background levels. We 
searched for such flaring intervals by creating a light curve with 
xmmselect, using the expression \((\text{PATTERN}==0)\&\&(\text{PI in} 
[10000:12000])\&\&(\text{FLAG}==0))\) and 100 s bins; we filtered 
out all intervals where the pn rate was >0.4 count s\(^{-1}\) using 
tagttigen. Flaring was substantial, with 75 ks of good time 
out of a 120 ks total.

We extracted the source spectrum from a region that 
was optimized by the analysis software; this was a circle 
with radius \( \sim 24'' \). A circular background region was chosen 
to be near the source, on the same chip, and at a similar off-axis angle; its radius was \( \sim 40'' \). These spectra 
were filtered by the good time interval, and by the expression 
\((\text{PATTERN}==4)\&\&(\text{FLAG}==0))\). We obtained a corre-
sponding response file with rmfgen and an ancillary response 
file with mkarf. The source spectrum was grouped to a mini-
num of 20 counts per bin, and energies outside the range 
0.3–10 keV were excluded.

2.3. Locating the X-Ray Source

We were unable to register the Chandra position of M31 
ULX2 directly with the HST observations due to a lack of known 
X-ray sources in the HST field. Instead we used 27 X-ray bright

---

\(^3\) http://www.stsci.edu/hst/acs/analysis/zeropoints/zpt.py
globular clusters (GCs) to register a combined ∼200 ks ACIS image (supplied by Z. Li) to the B-band Field 5 image of M31 provided by the Local Galaxy group Survey (LGS; Massey et al. 2006). We used pcf-iraf v2.14.1 to perform the registration, following the same procedure as described in Barnard et al. (2012a). The X-ray and LGS positions of the 27 X-ray bright GCs were determined using imcentroid; the equivalent FK5 coordinates were calculated for the X-ray and optical position of each GC using xy2sky v2.0, distributed with ftools. The X-ray positions of each GC were altered to match the LGS positions, allowing the registration of the merged Chandra image to Field 5 using the iraf task ccmap. This registration yielded σ position uncertainties of 0′.11 in R.A., and 0′.09 in decl. (Barnard et al. 2012a).

We then registered our first HST observation (H1) to the Field 5 observation in the same way using bright, unsaturated stars. Similarly, we registered our brightest Chandra observation of M31 ULX2 (C1) to the merged Chandra image using a selection of bright X-ray sources. The final uncertainties in the X-ray position of M31 ULX2 combine the position uncertainties in the X-ray image, the uncertainties in registering Observation C1 to the merged Chandra image, and the uncertainties in registering the merged Chandra image to the M31 Field 5 LGS image. The uncertainties in registering the HST observation were negligible.

3. RESULTS

3.1. Optical Analysis

3.1.1. Difference Imaging

The difference image produced from the H1 and H2 images revealed an optical counterpart at 00:42:43.699 +41:25:18.54 (J2000), with 1σ uncertainties of 0′.21 R.A. and 0′.18 decl. with respect to the LGS M31 Field 5 image. We present details of each HST observation in Figure 1, along with the difference image.

3.1.2. Photometry

We first obtained source counts in H1 for the ULX2 counterpart from FLT images 2 and 3 using PSF fitting via daofind: 1 and 4 were contaminated. For Frame 2, we obtained 1010 net source counts over 1255 s; the sky mean was 141 count pixel\(^{-1}\), with σ = 33 count pixel\(^{-1}\). For Frame 3, we obtained 1198 net source counts over 1410 s (sky mean = 166 count pixel\(^{-1}\), σ = 39 count pixel\(^{-1}\)). Individually, these frames gave a B magnitude of 26.03\(^{\pm0.03}\) and 25.95\(^{\pm0.02}\) respectively. Combining these frames yielded \(B = 25.97^{+0.03}_{-0.02}\). For consistency, we also checked the B magnitude derived from the DRZ image; this yielded a source intensity of 0.867 count s\(^{-1}\) over 5450 s (sky mean = −0.026 count s\(^{-1}\) pixel\(^{-1}\), σ = 0.011 count s\(^{-1}\) pixel\(^{-1}\)); the DRZ image gave \(B = 25.92^{+0.02}_{-0.01}\), consistent with the magnitude from our FLT images. We will use our B magnitude from the combined FLT frames \((B = 25.97^{+0.03}_{-0.02})\) for the rest of this work.

We saw no sign of the counterpart to M31 ULX2 in observation H2. Instead we estimated the 4σ upper limit to the B magnitude from the background counts; we note that 3 pixel radius circles used may be contaminated by neighboring stars, but this is not too important since we are only interested in upper limits. FLT images 1–3 yielded a total of 6829 counts over 3861 s; image 4 was contaminated by a cosmic ray. Hence, \(B > 28.4\) at the 4σ level.

The optical luminosity of the M31 ULX2 counterpart varied by at least ∼1 order of magnitude between observations. Using the value for \(N_H\) obtained from X4, \(M_V = -0.91\) for H1, and \(> +1.5\) for H2; the counterpart was more luminous (in terms of absolute magnitude) than any other transient counterpart found in M31 to date, apart from ULX1 (Barnard et al. 2012a); however, it was also fainter (in apparent magnitude) than any other counterpart due to the high absorption (see below).

The known counterparts of HMXBs in the Small Magellanic Cloud have absolute values \(-6 \lesssim M_V \lesssim -1\); for the known black hole HMXBs (Cygnus X-1, LMC X-1, and LMC X-3), \(-6.5 \lesssim M_V \lesssim -1.5\) (Barnard et al. 2011, and references therein). All of these high-mass systems are optically brighter than the M31 ULX2 counterpart even in outburst; hence a low-mass donor is likely.

3.2. X-Ray Analysis

We summarize the X-ray properties of M31 ULX2 during all the observations that we analyzed in Table 1. For each observation, we give the time since the first observation, the absorption, as well as the disk blackbody temperature and/or power-law photon index depending on the spectral state; the thermally dominated (TD) state was represented by the xspec model wabs*cflux*diskbb, while the SPL state was represented by wabs*(cflux*diskbb + cflux*powerlaw). Finally, we give the \(\chi^2/dof\), luminosity, and spectral state; luminosities assume a distance of 780 kpc (Stanek & Garnavich 1998). Values quoted without uncertainties are frozen. All uncertainties in results presented in this work are quoted at the 1σ level.

3.2.1. Re-analyzing the Swift Data

Following Henze et al. (2012c), we fitted S1–S5 simultaneously, with all of the parameters free to vary but tied between observations; we obtained similar results. However, we note that the number of degrees of freedom (dof) in our fits was substantially smaller than for the fits quoted by Henze et al. (2012c); this is probably due to different binning strategies. Our best simultaneous fit for a disk blackbody emission model yielded \(N_H = 2.87 \pm 0.15 \times 10^{23}\) atoms cm\(^{-2}\), \(kT_{in} = 0.877 \pm 0.016\) keV.
and $\chi^2$/dof = 377/332. When fitting a disk blackbody + power-law model, the photon index was frozen at 2.7, following Henze et al. (2012a): $N_H = 3.9^{+0.4}_{-0.5} \times 10^{21}$ atoms cm$^{-2}$, $kT_{in} = 0.85 \pm 0.02$ keV, and $\chi^2$/dof = 374/331.

The null hypothesis probabilities for the model fits to S1–S5 are 9% for Scenario A, and 10% for Scenario B. We caution that there is no statistical requirement for the addition of the power-law component to these relatively low-quality spectra; our motivation for including Scenario B is the discrepancy between the Scenario A light curve and our optical results the known behavior of Galactic transients (see below). We also note that our unabsorbed luminosities for Scenario B assume a particular power-law index (following Henze et al. 2012b, 2012c); Scenario B luminosities may therefore be subject to systematic uncertainties; however, our X4 spectrum is consistent with $\Gamma = 2.7$ at the $1\sigma$ level.

The 0.3–10 keV luminosity for the disk blackbody model for S1–S5 was $1.11 \pm 0.02 \times 10^{39}$ erg s$^{-1}$, while the two-component model yielded a luminosity of $1.5 \pm 0.3 \times 10^{39}$ erg s$^{-1}$. These two luminosities are consistent, due to the large uncertainties in the luminosity from the two-component model. In physical terms, the extended corona would appear brighter because cool photons in the outer disk are upscattered into the observed energy range.

In Figure 2, we present the best-fit unfolded Scenario B spectrum multiplied by energy for S4 (the highest quality Swift spectrum); the disk blackbody and power-law compo-

**Notes.** For each observation, we give the time from first observation, absorption normalized to $10^{21}$ atoms cm$^{-2}$, disk blackbody temperature, power-law photon index; we then give the corresponding $\chi^2$/dof, 0.3–10 keV luminosity normalized to $10^{37}$ erg s$^{-1}$, and spectral state. For C1 and S1–S5, we give fits pertaining to Scenarios A (TD) and B (SPL); S1–S5 were fitted simultaneously with all parameters tied. The quality of the spectrum is indicated by the degrees of freedom (dof), since each spectral bin contains at least 20 counts. For C8–C9, we assume a hard state emission model, with $N_H = 3.37 \times 10^{21}$ atoms cm$^{-2}$ and $\Gamma = 1.7$. All uncertainties are quoted at the $1\sigma$ level.

![Unfolded Spectrum](image-url)
the power-law contribution to zero increases the $\chi^2$/dof to 148/88, demonstrating that the power-law contribution is significant in this model; however, a single disk blackbody emission model fits this spectrum just as well, with $\chi^2$/dof = 99/88.

Our analysis of S6 supports that analysis reported by Henze et al. (2012c). Fitting an absorbed disk blackbody model yielded $N_H = 3.5 \pm 0.9 \times 10^{21}$ atoms cm$^{-2}$, $kT_{in} = 0.62 \pm 0.05$ keV, and $\chi^2$/dof = 19/18 with a 0.3–10 keV luminosity of $4.8 \pm 0.6 \times 10^{38}$ erg s$^{-1}$.

### 3.2.2. The X-Ray Evolution of M31 ULX2

The spectra of X2 and X3 have been interpreted in two ways. Henze et al. (2012b) used a disk blackbody + power-law emission model, and obtained a 0.3–10 keV luminosity of $\sim 2.5 \times 10^{39}$ erg s$^{-1}$ for X3. Alternatively, Middleton et al. (2012) used a disk blackbody + COMPTEL emission model with a 0.3–10 keV luminosity for X3 of $1.26 \pm 0.02 \times 10^{39}$ erg s$^{-1}$. We note that the fit obtained by Middleton et al. (2012) suggests a compact, optically thick, opaque corona, while the Henze et al. model represents an extended, optically thin corona (see, e.g., Barnard et al. 2011); we shall label these Scenario A and Scenario B, respectively.

Both scenarios agree on the following. The X-ray emission of M31 ULX2 evolved considerably during the outburst: it appears to have evolved from the hard state (HS) to a two-component emission state during the rise (X1–X3), either the “ultraluminous” state or something resembling the SPL state; we note that the true peak may not have been observed. It then went to the TD state in decline (X4, C2–C7, S6). A sudden drop in intensity at the end of the outburst (C8–C9) suggests a transition from the TD state (where the most of the bolometric luminosity is in the observed band) to the HS state (where much of the power can be emitted at much higher energies).

The difference between Scenarios A and B is in the interpretation of the spectra from C1 and S1–S5. These spectra are consistent with being in an SPL-like state (disk blackbody + power-law spectra), or in the TD state (disk blackbody emission only). The TD spectra for C1 and S1–S5 are only consistent with Scenario A; the SPL spectra are consistent with both scenarios due to large uncertainties.

For Scenario A, the shape of the 0.3–10 keV light curve is more linear than exponential, losing $5 \pm 5 \times 10^{36}$ erg s$^{-1}$ per day. However, Scenario B favors exponential decay, with a 0.3–10 keV e-folding time of $\sim 80$ days. Since X-ray transient decay is expected to be exponential or linear depending on whether or not the disk is fully ionized, Shahbaz et al. (1998) studied the dependence of lightcurve shape on orbital period and peak X-ray luminosity. For black hole transients with peak X-ray luminosities $> 10^{39}$, they expect exponential decay even for systems with periods $> 300$ hr. For Scenario A to be correct, the optical counterpart is expected to have $M_V \lesssim -5$ according to either Equation (1) or (2), and $B \lesssim 21$ according to Equation (4); this is considerably brighter than the observed magnitude, $B = 25.95^{+0.03}_{-0.02}$, hence we find Scenario A unlikely.

We present a light curve of 0.3–10 keV luminosities for M31 ULX2 in Figure 3, created using the results of Henze et al. (2012a, 2012b) and Middleton et al. (2012) in addition to our Chandra, Swift, and XMM-Newton results. We present only one datum for observations that both scenarios agree on: C2–C9, X4, and S6. Gray and black data correspond to Scenarios A and B, respectively, for X1–X3, C1, and S1–S5. X1–X3 are represented by open squares, X4 by a filled square, C1–C9 by circles, and S1–S6 by diamonds. Times of H1 and H2 are indicated by downward arrows.

We used our X4 0.3–10 keV pn spectrum of M31 ULX2 to get the best measurement of the absorption; we obtained $\sim 62,000$ net source counts. An absorbed disk blackbody provided an acceptable fit ($\chi^2$/dof = 689/636). This was slightly improved by adding a power-law component ($\chi^2$/dof = 684/634); absorption $N_H = 3.37^{+0.07}_{-0.05} \times 10^{21}$ atoms cm$^{-2}$, inner disk temperature $kT_{in} = 0.577 \pm 0.005$, photon index $\Gamma = 2.3^{+0.4}_{-0.2}$, quoting 1σ uncertainties. The total 0.3–10 keV unabsorbed luminosity was $4.07 \pm 0.10 \times 10^{38}$ erg s$^{-1}$, with $3.95 \pm 0.04 \times 10^{38}$ erg s$^{-1}$ contributed by the disk blackbody; this corresponds to the TD state (Remillard & McClintock 2006). We present this best fit to the pn spectrum in Figure 4.

While most of the absorption measurements are consistent with that from X4, we note that the spectral fits obtained by Henze et al. (2012a) for X2 and X3 suggest significantly higher absorption. Henze et al. (2012a) use a power-law component to represent the Comptonized emission component; this could overestimate the number of soft photons in the unfolded spectrum, thereby increasing the absorption required to produce observed spectrum. However, observations S1–S5, and C1 were also modeled with the same power-law component in Scenario B, and yielded $N_H$ values consistent with X4. Furthermore, the absorption obtained by Middleton et al. (2012) for X2 is 8σ higher than our absorption for X4. Hence the increase in absorption during outburst is likely to be real; this extra absorbing material may have been ejected during the outburst, and dissipated by the time of X4.

We also note that the absorption measured in the simultaneous fitting of S1–S5 in Scenario A is 3.0σ lower than that measured in X4, further evidence against Scenario A.
3.3. Estimating the Orbital Period

3.3.1. Scenario A

In Scenario A, the 0.3–10 keV luminosity of M31 ULX2 at the time of H1 was $\sim 9.7 \times 10^{38}$ erg s$^{-1}$, assuming a decrease of $\sim 5 \times 10^{36}$ erg s$^{-1}$ day$^{-1}$. Assuming the C1 TD spectrum (Table 1), this corresponds to a 2.0–10 keV luminosity $\sim 4.5 \times 10^{38}$ erg s$^{-1}$. Since M31 ULX2 is in the TD state for Scenario A, we may use Equation (2) to estimate the orbital period. The suggested orbital period is $11 \pm 8$ hr at the 1σ level, including uncertainties in the relation; this is clearly shorter than the $>300$ hr expected from the linear decay (Shahbaz et al. 1998).

3.3.2. Scenario B

For Scenario B, we estimated the 2–10 keV luminosity of M31 ULX2 at the time of H1 to be $\sim 4.0 \times 10^{38}$ erg s$^{-1}$. Using the relation specific to black holes, we obtained an orbital period of $8.5 \pm 0.4$ hr, not including uncertainties in the relation.

However, we note that M31 ULX2 is likely to have been in the SPL state during H1, whereas the black hole period relation (Equation (2)) is calibrated for TD spectra; the X-ray to optical ratio is likely to be different for different spectral states in the same system. Using Equation (1) results in an orbital period of $28.5 \pm 1.3$ hr; given that the sample used in deriving Equation (1) was dominated by neutron stars, and that black hole binaries with the same size disk have shorter periods than neutron star binaries, we consider this period to be some sort of upper limit.

A period for M31 ULX2 in the range $\sim 9$–30 hr is consistent with the period estimated for the first ULX in M31 (T9 in Barnard et al. 2012b, $P = 18^{+3}_{-5}$ hr).

4. DISCUSSION AND CONCLUSIONS

XMMU J004243.6+412519 (M31 ULX2) is the second ULX to be observed in M31; both of these systems are transient. We have combined analysis of our *Chandra*, *HST*, and *XMM-Newton* observations of M31 ULX2 with the re-analysis of *Swift* data and reported results of Henze et al. (2012a, 2012b, 2012c, 2012d) and Middleton et al. (2012) to build a picture for the system.

We have identified an optical counterpart by its change in $B$ magnitude from 25.97 to $>28.4$ ($M_V$ from $-0.91$ to $>-1.5$). Hence, the optical emission is dominated by reprocessed X-rays from the disk. Since even the peak optical emission is fainter than known HMXB counterparts, a low-mass donor is expected. We estimate an orbital period of $\sim 9$–30 hr; this period is comparable with that estimated for the first M31 ULX.

Two solutions were presented for fitting the spectra from the highest luminosity observations. Middleton et al. (2012) used a disk blackbody + Comptonization model that represented a typical “ULX state,” with a cold, optically thick corona that obscures the inner regions of the disk (Gladstone et al. 2009); we refer to this as Scenario A. Henze et al. (2012b) used a disk blackbody + power-law model that represents a hot, optically thin corona that extends much of the accretion disk (Barnard 2010); we refer to this as Scenario B. Scenario A results in a linear decay light curve, while Scenario B yields an exponential decay light curve. For X-ray luminosities $>10^{39}$ erg s$^{-1}$, linear decay is only expected for systems with periods $\gg 300$ hr (Shahbaz et al. 1998). Since our orbital period estimate is $\sim 9$–30 hr, we favor Scenario B for this system. However, we caution that there is no statistical evidence in the X-ray spectra that Scenario B is superior. Furthermore, the Scenario B luminosities assume $\Gamma = 2.7$, so the luminosities may be subject to systematic uncertainties.

Since this work provides further support for spectral models where the Comptonized component dominates the low energy emission (on top of, e.g., Barnard 2010; Barnard et al. 2011), we consider how this could be possible. We are assuming unsaturated, inverse Compton scattering of cool photons on hot electrons in the corona; the mean number of scatterings experienced by the photons is much less than the number of scatterings required to bring the photons up to the electron energy (see, e.g., Sunyaev & Titarchuk 1980, and references therein). If the soft excess is due to Comptonization of disk photons, the lower energy photons must be scattered more often than the high energy photons. This could be achieved if the corona density decreased in the inner disk region due to increased radiation pressure; the high energy photons in the inner disk would experience fewer scatterings than the low energy photons in the outer disk.

The spectral evolution of M31 ULX2 was unusual in that it went from something like the SPL state to the TD state during the decay. However, we note that the spectrum reported for X3 (the observed peak) by Henze et al. (2012a) is similar to the spectra exhibited by NGC 253 ULX1, which in turn resembles the black hole + Wolf–Rayet binary IC10 X-1 (Barnard 2010). The properties of those systems suggested extended coronae, and we proposed that many ULXs could be explained by stellar mass black hole systems with truly super-Eddington accretion overall, while the local accretion rate remained sub-Eddington. It is intriguing that in all of the observations where M31 ULX2 is super-Eddington, its spectra were reminiscent of the SPL state. However M31 ULX2 does appear to be consistent with a low-mass XB containing a $\sim 10 M_\odot$ black hole.

It is interesting to compare the outbursts of the two transient ULXs in M31. The outburst of the first transient ULX appears to have been more traditional, going from the HS to the TD state during the rise, then to the SPL and back to the HS state during decay; indeed it even exhibited a TD state at a 0.3–10 keV...
luminosity of $1.75 \pm 0.07 \times 10^{39}$ erg s$^{-1}$ (Nooraee et al. 2012). M31 ULX1 is also a low-mass XB, but the mass of the black hole appears to be somewhat higher than usual.

We thank the anonymous referee for his/her thoughtful comments that substantially improved this paper. We thank Z. Li for merging the Chandra data. This research has made use of data obtained from the Chandra data archive, and software provided by the Chandra X-Ray Center (CXC). We also include analysis of data from XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA member states and the US (NASA). R.B. is funded by Chandra grants GO2-13106X and GO1-12109X, along with HST grants GO-11833 and GO-12014. M.R.G. and S.S.M are partially supported by NASA contract NAS8-03060.

Facilities: CXO (ACIS), HST (ACS), XMM (pn), Swift (XRT)
