Biostoning of textile effluent with laccase enzyme

K. Iqbal², A. Nadeem¹* and U. Zafar²

¹CSIR Labs, Pakistan
²PCSIR Labs, Lahore, Pakistan

Abstract

The incessant release of textile effluent comprehending dyes and heavy metals which impacts on aquatic life. Current study used an enzyme to eradicate phenolic compounds and synthetic dyes from textile effluent by an indigenously isolated white rot fungus Pleurotus ostreatus- P1 has been cultured and indicated the utmost laccase activity with synthetic medium; as reacting substrate for dye decolorization. The textile effluent decolorization optimization has been conducted with different concentrations of laccase enzyme, temperature and pH. The 90% effluent decolorization was obtained by applying response surface methodology (RSM) conditions temperature, crude laccase enzyme and pH, 25°C, 13.5 U/ml and 5 respectively. The predicted values were validated with experimental values that confirms the steadiness of the model.

Keywords: Crude enzyme; Textile; Decolorization; RSM; Laccase

Introduction

The adulteration of water bodies in Pakistan by synthetic dyes from textile is one of the thorniest and global environmental issues. These dyes and their breakdown products disposal into receiving streams is very threatening, toxic and carcinogen potential could lead to derogatory effects on both aquatic ecosystem and eventfully human beings through the food chain. The common practices in developing countries like Pakistan most of the textile industries discharge their daily effluent without or after partial physical/chemical treatments into main water bodies of localities makes the effluent more difficult to treat due to high BOD, COD, colour, pH and other carcinogenic heavy metals.

These dyes are highly resistant to degradation and its management by adsorption, chemical oxidation, electro-chemistry, membrane filtration, ion exchange, ozonation and phytochemical techniques have some disadvantages due to long processing period, low efficiency and cost prohibitive. There is an insistent need to develop new and effective ecofriendly biological treatment for textile effluent. Recent studies and literature is available on bioremediation by fungi or their enzymes to detoxify and complete mineralization of dye end products. Enzymes (Laccase and peroxidase) decolorized dyes more rapidly and retained its activity even under unfavorable conditions (Arias et al., 2016). It is biotechnologically important enzyme due to low substrate specificity, culture conditions, fermentation mode and its production may varied due to nutrients and inducers (Birhanl and Yesilada, 2013). Laccase, obtained from different strains and fermentation process, have different dye decolorization ability. It has been reported that laccase derived from Pleurotus ostreatus decolorized 70% malachite green and bromophenol blue also decolorized by laccase produce by Trametes sp.420. Moreover laccase efficiency can be increased by the addition of ABTS mediators because it catalyze phenolic, polyphenol and aromatic amine compounds (Unuofin et al., 2019).

To apply this ecofriendly technique required a number of experiments to optimize different process parameters for...
textile effluent treatment can results time consumption and cost elevation. It is not an easy chore because various factors are involved during effluent decolorization. Several authors have conducted single-factor optimization to evaluate the optimum process conditions. This method is erratic and may lead to misapprehension of results and it does not illustrate the interactive effects among the variables and guarantee the determination of optimal conditions (Mannan et al., 2007). To overcome these limitations a statistical experiment (RSM) was designed for the optimization of process parameters to treat textile effluent.

Response surface methodology (RSM) is a multivariate technique used for developing, improving, and optimizing the process to evaluate the relative significance of different process parameters. It is comprehensively studied in various biotechnology fields i.e optimization of medium composition, fermentation and food processing (Sonica and Kiranjot, 2019). Jadhav et al. (2013) applied the RSM for the decolorization of dyes from water and found encouraging results during their study. However few literatures have been reported for the decolorization of dyes by enzymatic catalysis with RSM technique.

Consequently, the main objective of present study was to investigate the impact of laccase concentration, pH and temperature on textile effluent decolorization.

Materials and methods

Collection of organism for enzyme production

Pleurotus ostreatus- P1 (laccase enzyme producing organism) was collected for the treatment of textile effluent. Its fruit body was collected from the Horticulture Department, University of Agriculture, Faisalabad, Pakistan. The surface sterilization was conducted with hydrogen peroxide into petri plates contained Kirk medium (Tien and Kirk, 1988) and incubated at 28°C. (Fig.1).

![Fig 1. (a) Culture plate of Pleurotus ostreatus-P1 (b) Staining by guaiacol (c) Staining by syringaldazine](image)

Production of laccase by Pleurotus ostreatus- P1

The mycelia of Pleurotus ostreatus- P1 after seven days of incubation was isolated and stored under controlled environmental conditions at 4°C and incubation the synthetic media (ammonium citrate: 10 g/l; yeast: 0.5 g/l; glucose: 10 g/l; KH₂PO₄: 1.0 g/l; MgSO₄: 0.5 g/l; KCl: 0.5 g/l) was prepared in 250 ml conical flask by using 150 ml double distilled water and its initial pH was adjusted at 5.5 with 0.1 M sodium acetate buffer before autoclaving (temp:121°C; time: 20 min, pressure:1.5 atm). Hereafter media was inoculated with 4mm agar block having seven days old culture of Pleurotus ostreatus-P1 for enhanced laccase production and liquid culture broth of this media was centrifuged at 4000 rpm at 4°C for 20 min to get clear supernatant for enzyme assay.
Table I. Characteristics of textile effluent

| Level | pH | Temperature (°C) | Laccase activity (U/ml) |
|-------|----|------------------|-------------------------|
| -1    | 5  | 15               | 7                       |
| 0     | 6  | 25               | 10.5                    |
| +1    | 7  | 35               | 13.5                    |

Table II. The level of variables chosen for decolorization

| Parameters | Before treatment | After treatment | NEQS |
|-----------|------------------|-----------------|------|
| Colour (Pt-Co) | 670              | 67              | colorless |
| pH        | 11.4             | 6.45            | 6-10  |
| BOD (mg/l)   | 546.32           | 164             | 80    |
| COD (mg/l)   | 894.56           | 295             | 150   |
| TDS (mg/l)  | 567.0            | 156             | 3500  |
| TSS (mg/l)  | 453.0            | 118             | 150   |

Table III. The Box-Behnken design for three independent variables for color decolorization

| Run order | pH  | Temperature | Laccase activity |
|-----------|-----|-------------|------------------|
| 1         | +1  | -1          | 0                |
| 2         | -1  | -1          | 0                |

| 13        | +1  | 0           | +1               |
| 14        | 0   | +1          | -1               |
| 15        | 0   | -1          | +1               |
Treatment of textile effluent

The textile effluent was collected from style textile having the pollutant concentration pH: 11.4; colour: 670 Pt-Co; BOD: 546.32 mg/l; COD: 894.56 mg/l; TDS: 567 mg/l; TSS: 453 mg/l were treated by applying the crude laccase enzyme under controlled pH and temperature (Table II).

Dye decolorization was performed as per experimental design RSM; Laccase concentration (7, 10.5, 13.5 U/ml), temperature (15, 25, 35°C) and pH (5,6,7) (Table I). The pH of the decolorizing solution was adjusted with the addition of di-sodium hydrogen phosphate buffer for pH 5, 6 and 7. It was processed in 250 ml Erlenmeyer flask containing phosphate buffer (25mM), crude enzyme and 50 ml volume of dye effluent as per experimental design RSM for the period of 40 min. The mixture was further stirred for 4h on the shaking bath and final absorbance was recorded. A control test was also performed in parallel along with industrial effluent.

Optimization of textile effluent decolorization by response surface methodology (RSM)

Three experimental factors pH, temperature and laccase activity were denoted as X₁, X₂ and X₃ correspondingly at three different levels (+1, 0, -1). These three variables were considered as momentous in dye degradation/decolorization, ranges of which were accomplished from single dye experiment. The temperature and pH are the factors, affect the reaction rate whereas buffers are the enzyme mediators and surfactants. The low, middle and high levels of each variable were designed as -1.0,+1 respectively and listed in Table II and Table III. The three significant variables X₁, X₂, X₃ and the mathematical relationship of the response Y to these three variables was approximated by the quadratic model equation as follows:

\[ Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_{11} X_1^2 + \beta_{12} X_1 X_2 + \beta_{13} X_1 X_3 + \beta_{22} X_2^2 + \beta_{23} X_2 X_3 + \beta_{33} X_3^2 \]  

(1)

where Y - predicted response; \( \beta_0 \) - constant; X₁-pH; X₂-temperature; X₃- laccase activity; \( \beta_1, \beta_2 \) and \( \beta_3 \) linear coefficient; \( \beta_{11}, \beta_{22}, \beta_{33} \) - quadratic coefficient; \( \beta_{12}, \beta_{13}, \beta_{23} \) - cross-coefficient.

The preset ranges of independent variables for dye decolorization optimization:Laccase concentration (7, 10.5, 13.5 U/ml), temperature (15, 25, 35°C) and pH (5,6,7) (Table I).

A total number of 15 experiments were obligatory to determine the 10 coefficient in the quadratic model equation.

In this study, experiments were run in duplicate i.e. 30 experiments were carried out to calculate approximately 10 coefficients for the decolorization of dyes. Design permits to establish the linear and quadratic models, determine the accuracie by comparing lacks of fit of model and coefficient of determination R². The statistical analysis were performed using multiple regression and one way 'Analysis of Variance (ANOVA).

The decolorization capacity (Qₑ) and removal percentage of effluent were determined by using the following equations.

\[ Qₑ = \frac{Co-Ce}{W} \times V \]  

(2)

\[ R(\%) = \frac{Co-Ce}{Ce} \times 100 \]  

(3)

where Qₑ (mg/g) was the capacity of dye degradation, Co (mg/l) was the initial concentration and Ce (mg/l) was the concentration at time t, V (l) was the initial volume of dye solution and W (g) was the amount of enzyme used.

Analytical techniques

Laccase assay

Laccase activity was determined by enzymatic oxidation of syringaldazine spectrophotometrically at 525 nm (\( \epsilon = 12 \times 100/M/cm \)). The assay mixture has 850 μl of 0.1 M sodium citrate (pH 5), 100 μl of syringaldazine (0.1 mM) and 50μl of fungal broth supernatant. One unit of enzyme activity was defined as the amount of enzyme which caused an increase of one in the absorbanece per min under assay condition (Li et al., 2008). Similarly laccase activity was also determined by guaiacol oxidation at 450 nm (\( \epsilon = 12 \times 100/M/cm \)). The reaction mixture contained 3 ml acetate buffer (10 mM, pH: 5), 1 ml guaiacol (2 mM) and 1ml supernatant and U/ml was calculated.

Effluent parameters

The effluent samples were treated as per experimental design (RSM) and their characteristics were analyzed. The samples were collected from experimental flask and determined the color, pH, COD, BOD, TDS and TSS.
**Statistical analysis**

In order to reduce the errors during dye decolorization/degradation and enzyme assay each experiment was conducted in triplicate under identical conditions and then mean and standard error (S.E) values were obtained. S.E has been displayed as a Y-errors bar in figures by using MS-2010 along with color decolorization by RSM was applied by using software Mintab.16.

**Results and discussion**

Laccase was a unique enzyme; its production can be enhanced for industrial scale by optimization of physiological and nutritional synthetic media. The foremost cause of screening fungi *Pleurotus ostreatus*-P1 for laccase production was due to its importance as an efficient source of laccase (Alba et al., 2019). The presence of laccase was confirmed by the formation of reddish brown and dark purple zone due to the oxidation of Guaiacol and Syringaldazine (Wang et al., 2008).

The white rot fungi (enzymes) have the ability to decolorize the effluent color which was proportional to the removal of chromogen. The decolorization percentage in present study was 90 at optimized temperature and pH. In addition decolorization percentage was increased as the quantity of laccase enzyme increased. Similar observations have been found on co-relationship between ligninolytic enzymes and textile dye decolorization (Patel et al., 2009). It has been reported that concentration of dye effect the removal percentage of color by laccase enzyme. It was clear from these results white rot fungi (Basidiomycetes) along with other species have the ability to reduce or decolorize the color of dyes in proficient form. It was also noted that pure laccase enzyme did not decolorize the effluent completely due to absence of mediators.

In textile industry, different process including caustic scouring, bleaching, mercerization and dyeing are running parallel that impact on the pH of effluent. pH was a requisite parameter for biological treatment of effluent because microbes mechanized between pH 6-8. During this study the pH of the sample meets the NEQS after treatment, whereas effluent showed that the highly basic salts has been used in dying process (Table II).

The total suspended solids (TSS) based on the nature of chemical and physical process continuing in the industry. These are not filter from the common filter paper and hinder the microbial activity, which ultimately reduce the mechanism of decolorization of dyes.

Presently the decolorization was enhanced by the reduction of TDS up to 72.5%. It depicted that reduction in TDS means white rot fungi producing enzymes have the proficiency to lessen the dye color in more precise way than chemical process. The similar observation has been found in case of TSS due to the same nature of inorganic salts. These are aesthetically inadequate for human besides the ecosystem (Patel et al., 2009).

![Decolorization of textile effluent by response surface methodology (RSM) under experimental conditions of pH, temperature and laccase concentration](image-url)
from textile is one of the thorniest and global environmental problems. The adulteration of water bodies in Pakistan by synthetic dyes is a serious concern. Most of the textile industries in Pakistan discharge their daily effluent without or after partial physical/chemical treatments like electro-chemistry, membrane filtration, ion exchange, etc., due to cost and technical considerations. There is an insistent need to develop processes that are environmentally friendly and cost-effective.

To examine the impact of laccase enzyme amount on dye decolorization, different amounts of crude enzyme were used. It was concluded that 13.5 U/ml of laccase was sufficient for optimal decolorization. The percentage removal of dye depended on the source and concentration of enzyme, and the equilibrium was attained. The decolorization rate was found to be higher in synthetic media than in natural media. Enzyme concentration was optimized to enhance the decolorization rate.

The presence of laccase was confirmed by the appearance of blue coloration in the assay mixture containing syringaldazine and hydrogen peroxide. The decolorization percentage in the present study was higher than that reported in literature for the decolorization of dyes from water and effluent. Its fruit body was collected from the Horticulture Department, and it was incubated at 28°C. (Fig.1).

A Box-Behnken design under RSM was used to analyze the effects of decolorization optimization: Laccase concentration (7, 10.5, 13.5 U/ml), temperature (15, 25, 35 ºC), and pH (4, 5, 6) on the decolorization rate. The dependent variables were Y = decolorization percentage, X1 = laccase activity, X2 = temperature, and X3 = pH. The mathematical relationship of the response Y was established using the quadratic equation with the total variation being defined by this model. The p-value of the calculated F (50.37) and low probability (F=0.0001) show that the model was significant. The value of adjusted R2 (97.11%) suggests that 97.11% of the variation in Y is explained by the model. The standard deviation of the estimated response was 1.638.

The results of the analysis of variance (ANOVA) for the decolorization of dyes are presented in Table V. The regression model was significant (p-value < 0.05). The coefficients of the model were calculated, and the significance of each term was evaluated. The terms Coef SE Coef T p values are shown in Table VI. The regression co-efficient of the model for dye decolorization is given in Table VII. The terms Coef SE Coef T p values are shown in Table VII.
COD and BOD are the upright indicator of degradable material which reasons of aesthetic smell the surrounding. In this study the reduction of BOD and COD was 70% and 67% respectively and reduction in BOD and COD enhanced as the concentration of laccase enzyme augmented with suitable temperature and pH. It depicted that the activity of enzyme increased when the pH of medium will be 5 and temperature will 25°C. So it can be concluded that laccase enzyme reduce the color and other pollutant concentrations according to the lines of NEQS.

Decolorization of textile dye by whole culture broth of Pleurotus ostreatus-P1

The laccase produced by Pleurotus ostreatus-P1 was used to evaluate the oxidation of dye at different temperatures, pH and decolorization was noted at different time intervals (Fig 2).

A Box-Behnken design under RSM was used to analyze the interactive impact of pH, temperature and laccase units on decolorization. The base point for the design was selected from single parameter study in decolorization process under controlled conditions.

The selected levels of independent variables used in experiment are given in Table IV. Fifteen experimental runs were carried out according to Box-Behnken design three variables; pH, temperature and laccase units. Various combinations of three variables and the decolorization percentage of dye in each case are presented in Table IV. The quadratic equation was fitted to the above data by using multiple linear regressions by software design expert techniques.

\[ Y = -485.1222 + 102.575X_1 + 10.0475X_2 + 28.3214X_3 - 7.71250X_1^2 - 0.170125X_2^2 + 0.0675000X_1X_2 - 1.80000X_1X_3 - 0.1428574X_2X_3 \]  

(4)

The goodness of the model was checked by the coefficient of determination \( R^2 \) and adjusted \( R^2 \) (multiple correlation co-efficient R). The value of adjusted \( R^2 \) (97.11%) suggest that the total variation of 97.11% of decolorization is accredited to the independent variable and only 0.45% of the total variation could not be defined by this model. The values of adjusted \( R^2 \) near to 1 explain the better correlation between the experimental and predicted values. The predicted \( R^2 \) of 83.46% was in realistic form with adjusted \( R^2 \) of 97.11% between the experimental and predicted values of decolorization. The corresponding coefficients are significant when the \( t \)-values are smaller whereas the \( p \)-values are larger as are presented in Table VI. In this case coefficient \( X_1 \), \( X_2 \) and \( X_3 \) were examined to be highly important model terms. The coefficient of interaction terms \((X_iX_jX_k)\) of temperature and laccase units was found to be highly significant. The decolorization results of reactive dyes and its analysis of variance are presented in Table-V. It defined the quadratic model by one way ANOVA and the calculated values of F (50.37) and low probability (F=0.0001) show that the model was significant. It was also noted from Table VI the coefficient for the square effect (p=0.0001) and interaction effects of all parameters were highly significant when compared with linear effects.

The laccase produced by Pleurotus ostreatus was used to evaluate the oxidation of dye at different temperatures and pH value. The crude laccase from Pleurotus ostreatus decolorize anthraquinone more efficiently than azo dyes. The laccase from Pleurotus ostreatus causes dyes decolorization because of dyes structure which results in difference in substrates specificity. Similar results were obtained from laccases from T. hirsuta, T. versicolor and Polyporus pinisitus. When an azo dye was oxidized by a laccase, it cleaves the azo linkage of phenoxy radicles and release molecular nitrogen. As a result, the decolorization of azo dyes occurs and toxic aromatic amine was excluded.

The application of response surface technology to examine the effect of laccase from Pleurotus ostreatus, pH and temperature on decolorization was completed. A quadratic equation was established to demonstrate the relationship between decolorization percentage and three variables of the design. The experimental values were in line with predicted values and the model was highly significant with the correlation coefficient. The limitation for the use of Pleurotus ostreatus cultures for decolorization was the acidic pH range for the activity which was similar to other white rot fungi. Effluents from textile industry always contain mixed dyes and mostly show high pH in the presence of auxiliary dyeing compounds which are not favored to the culture liquid and purified laccase from white rot fungi in term of dye decolorization because low pH was essential in fungal growth medium for their metabolic activity. However, Pleurotus ostreatus culture liquid was able to decolorize not only the synthetic dye solutions at acidic pH but also synthetic dye both at high pH and low temperature. The Box-Behnken and central composite experiment designs were applied in decolorization by laccase from P. sajor-caju and T. pubescens respectively with the addition of HBT as mediator and biodegradation of reactive dye (Veroxif Red) by P. chrysosporium. The Box-Behnken results revealed that decolorization obtained up to 90% when the temperature, crude laccase enzyme and pH were 25°C, 13.5 U/ml and 5 respectively.
The pH of solution was an imperative element because it impacts on the chemical properties of dye molecules and on mechanism of adsorption process. It takes part on activity of functional group on adsorbent surface as well as competition of dye molecules for bonding with hydrogen molecules of adsorbents. In this study the amount of dye removal was analyzed to optimize the pH of solution under the range of pH 5-7 and fixed concentration of crude laccase enzyme (13.5U/ml) for the period of 40 min under 25°C temperature; results obtained are presented in Fig. 3a. As seen from Fig. 3a removal of dye concentration was increased with decreasing the initial pH of solution from 5-7 and maximum removal percentage was attained under the pH 5. It is due to the difference of redox potential of dyes with the active site of laccase enzyme. The redox potential was an important factor and the production of laccase from different fungi has different redox potential. The decolorization with laccase enzyme depends on the enzyme source (species) chemical structure of dye and reaction conditions (temperature, crude laccase enzyme concentration, pH and time). The lesson in color due to pH was retained on the same pattern in all concentration of dye solutions (20, 30, 50 mg/l) in this study. These results are in agreement with Yesilada et al. (2014).

The impact of temperature on decolorization of dye by crude laccase enzyme was investigated under three temperatures namely 5,15 and 25°C. When temperature of incubation was increased the decolorization of dye was also raised up to certain limit and then decline in their behavior due to the activity of laccase enzyme inhibited at higher and lower temperature. The highest removal was attained at 25°C, 95.4%, 94.86%, 93.6% more than 5°C for 50,30,20 mg/l respectively. Most of white rot fungi (WRF) enzymes

![Image 3. Effect of different factors on color removal (a) pH (b) Temperature (c) Laccase concentration (d) Time]
having optimum temperature for colour removal ranged from 25-37°C for different dye stuffs. It has been cited in literature WRF like P.chrysosporium and Corious versicolor give maximum dye removal at 35°C, whereas below 25 and above 40°C inhibit the fungal growth and lignolytic enzymes production. Liu et al. (2013) reported that the purified and crude laccase enzyme have been found an effective dye removal agent. Similar observations have been found in this study (Fig 3b).

To examine the impact of laccase enzyme amount on dye decolorization, different amounts of crude enzyme were exercised to inoculate the triplicate decolorization flasks, were incubated for stipulated time period under optimized pH (5) and temperature (25°C). The amount of enzyme affects the decolorization percentage positively and it increased as the concentration of enzyme increased depicted in Fig.3c but sometimes increase in enzyme size/ amount reduce the decolorization due to early exhaustion of nutrients. The percentage removal of dye was maximum by 13.5 U/ml, which was 34.8% more than 7 U/ml for 20 mg/l effluent. Similarly 21.4%, 17.34% and 13.4% more than 10.5 U/l for 50,30 and 20 mg/l respectively. In addition, similar to our finding Kumar et al. (2010) reported 4 % (v/v) optimum inoculum density for textile waste water decolorization. It was also stated in literature laccase exhibited the promising and great potential for decolorization of dyes in waste effluent (Birhanl and Yesilada, 2013).

In order to optimize the time for the decolorization of synthetic dye solution (20 mg/l) by laccase enzyme under optimize pH (5), laccase concentration (13.5 U/ml) and temperature (25°C). It was noted that maximum decolorization occurred within first 40 min, thereafter the equilibrium was attained. The decolorization rate depended on the source and concentration of enzyme, structure of dye, time for action, pH of medium and temperature. The peak reduction in color in initial stage may be the maximum utilization of laccase enzyme (Fig.3d).

Conclusion

The laccase enzyme was isolated from local strainPleurotus ostreatus- P1; enhanced its production by synthetic media. Enzyme concentration was optimized by RSM and check its efficiency for the decolorization of textile effluent. It was found Laccase has the potential to degrade the aromatic and other substrate present in effluent. It was concluded that 13.5 U/ml of laccase enzyme caused 90% color removal from textile effluent. So this can also be applied for biostoming in textile industry.
