We propose an experiment to look for possible small violations of the symmetrization postulate of Quantum Mechanics, in systems composed by three identical particles. Such violations could be detected by investigating the population of particular roto-vibrational states of symmetrical molecules containing three identical nuclei. We discuss the symmetry properties of such states, and the implications of the symmetrization postulate and of the spin-statistics. A high sensitivity spectroscopic investigation on simple molecules such as SO$_3$, BH$_3$ and NH$_3$ could lead to the first test of the symmetrization postulate for spin-0 and spin-1/2 nuclei.

I. INTRODUCTION

In the latest years, the possibility of small violations of the symmetrization postulate (SP) and the spin-statistics connection has been addressed from both the experimental and the theoretical point of view. The SP is at the basis of the quantum-mechanical description of systems composed by identical particles, asserting that only wave functions completely symmetric or antisymmetric in the permutation of the particles labels can describe physical states. In principle there would be no arguments against the existence of states with different symmetries, although they lack some of the properties which are peculiar of the completely symmetric and antisymmetric states. The only strict requirement that can be derived in a formal way in Quantum Mechanics is the so called superselection rule, which forbids transitions between different symmetry classes.

In addition, the experimental observation seems to indicate so far a well defined connection between the spin of the particles and the symmetry properties: half-integer spin particles can be described only by antisymmetric wave functions, while integer-spin particles by symmetric wave functions only. According to their behavior in a statistical ensemble, the two kinds of particles are indicated respectively as fermions and bosons.

Although both the SP and the spin-statistics connection seem to hold in the physical world, there is great interest in investigating possible very small violations, not detected so far. In case of two-particles systems, only the symmetrical and antisymmetrical states can be defined, and therefore the SP is redundant. As a matter of fact, the experimental tests of symmetry reported so far have been limited to the investigation of states containing only two identical particles, looking for violations of the usual connection between spin and statistics. In particular the latest high-sensitivity experiments of this kind have been performed on both fermionic systems, namely electrons, and bosonic systems, such as photons and oxygen nuclei. In the case of electrons, the existence of totally symmetric states in the spectrum of atomic helium has been searched [1], and the negative result of such investigation led to the establishment of a bound to the degree of violation of the spin-statistics, i.e. to the presence of exchange-symmetric electrons. A different experiments was performed on a metallic Cu sample [2], looking for the presence of any of the electrons in the conduction band with no symmetry requirements with respect to the electrons in the already filled shells. This can be considered a one-particle test of the identity of the electrons, which is even a more general property of the particles, but not a test of their symmetry. Results which are conceptually identical to the first case have been obtained for bosonic particles, by searching for an exchange-antisymmetric two-photons transition in atomic barium [3], and for rotational states in molecular oxygen [4, 5] and carbon dioxide [6] which are antisymmetrical in the exchange of O nuclei. The principle of all these experiments was to look for particular atomic or molecular transitions, whose probability would be zero according to the usual spin-statistics, by using high sensitivity spectroscopic detection techniques. The extrapolated bounds on the relative weight of the wrong statistics are almost at the level of $10^{-9}$ [7]. Reviews of different experiments which have been proposed, and interpretations of the results of various measurements as tests of the statistics, can be found in [8-10].

Theoretical studies of possible violations of the usual symmetry properties have focused on systems composed by a non-fixed number of particles, which can be treated within the Quantum-Field Theory formalism. In such context the spin-statistics connection is no more a postulate dictated by the experimental observation, but it can be rigorously proved through the spin-statistic theorem [11-12], the main assumption being the validity of the SP. Several theories allowing for small violations of such postulate have been proposed [13], and one of the most successful is based on the $q$-mutator algebra [14], in which deformed bilinear commutation relations are used in place of the ordinary ones. In this way it is possible to define exotic symmetries as a smooth interpolation
between the symmetric and antisymmetric ones, or statistics interpolating between the Bose and Fermi cases. By assuming the validity of this algebra it has also been possible to translate the bound on the spin-statistics for oxygen nuclei [7] into a bound on the statistics of the nucleons composing the nuclei [3] or, more generally, to establish a relationship between constraints on different kinds of particles [16].

To summarize, so far experiments have been devoted to search possible violations of the spin-statistics in simple systems, while theories allowing for violations of the more fundamental SP were focused on much more complex systems, which cannot be easily investigated experimentally. We note that no rigorous theoretical study of a simple quantum-mechanical system allowing for violations of the SP has been reported so far, although possible experiments on multi-particle molecular systems have been indicated [4,10].

In this paper we propose an experiment to be performed on molecular systems containing three identical nuclei, to search for possible violations of the SP in a system described within the quantum-mechanical theory. For this purpose, in Section II we briefly recall the concept of identity of particles, and the permutation properties of identical particles; we also recall that at least three particles are needed to define symmetries different from the usual ones. Then, in Section III, we discuss the properties of particular rotational states of symmetrical plane molecules with three spin-0 nuclei, which are forbidden by the SP, and with three spin-1/2 nuclei, which are forbidden by both the spin-statistics connection and the SP. We show that, nevertheless, such states have the proper symmetry to be defined consistently in a more general quantum-mechanical theory which does not include the SP. In Section III we briefly discuss how to test the possible small symmetry violations. Finally, in Section IV, we propose a high-sensitivity spectroscopic investigation to be performed on selected transitions of SO$_3$ molecule, and of BH$_3$ and NH$_3$ molecules, which best represent the prototypical molecule respectively for the spin-0 and spin-1/2 cases treated above. In the latter case, such states could be investigated in search of small violation of the statistics or of the symmetry of protons.

II. THE INDISTINGUISHABILITY OF IDENTICAL PARTICLES AND THE SYMMETRIZATION POSTULATE

A. General discussion

The indistinguishability of identical particles is one of the principles lying at the basis of Quantum Mechanics. It states that given a system of particles belonging to the same species (i.e. which have the same physical properties, like mass, charge, spin, etc.), a permutation of such particles cannot lead to any observable effect [18]. To discuss the implications of such principle, here we briefly recall some properties of a system containing $N$ identical particles (for a general discussion see for example Ref. [18,17,19]).

To each observable of the system is associated an hermitian operator $\hat{A}$, which can be written as

$$\hat{A} = A(\{\hat{O}_1\}, \cdots \{\hat{O}_N\}) \equiv \hat{A}(1, \cdots , N)$$

(2.1)

where $\{\hat{O}_j\}$ is a set of single-particle observables. In the same way, the vector

$$|1, 2, \cdots, N\rangle$$

(2.2)

represents a state where the first particle is characterized by a set of quantum numbers $\{1\}$, the second by $\{2\}$, and so on. Moreover we can define the permutation operators as

$$\hat{P}_{j_1,j_2,\cdots,j_N} f(1,2,\cdots,N) = f(j_1,j_2,\cdots,j_N)$$

(2.3)

and these operators form the symmetrization group $S_N$. Therefore, since a permutation of identical particles cannot be observed in any experiment, all quantum observables must be permutation-invariant

$$[\hat{P}, \hat{A}] = 0$$

(2.4)

and since the evolution operator $\hat{U}(t)$ is related to the Hamiltonian of the system $\hat{H}$, which is a physical observable, the above condition is fulfilled at any instant of time

$$[\hat{P}, \hat{H}] = 0 \implies [\hat{P}, \hat{U}(t)] = 0.$$  

(2.5)

An important consequence of these relations is that the Hilbert space $\mathcal{H}$ can be written as a direct sum of hortogonal subspaces, each one invariant under the permutation group, the hortogonality being preserved along the evolution of the system, and following a physical measurement. This result can be stated as a super-selection rule which forbids transitions between states transforming under inequivalent representations of the permutation group.

To investigate in detail the symmetry properties of a generic state of the system under permutation, it is convenient to introduce the operator of a cyclic permutation

$$\hat{P}_{(k_1,k_2,\cdots,k_K)} f(k_1,k_2,\cdots,k_K) = f(k_2,\cdots,k_K,k_1)$$

(2.6)

and the exchange operators of two particle, $\hat{P}_{(j,k)}$ (they are a particular case of the former), which are hermitian and unitary, with eigenvalues $\epsilon_{j,k} = \pm 1$.

Each generic permutation can be written either as the product of exchange between two particles, or of cyclic permutation of distinct elements, in the form

$$\hat{P}_{\text{cyclic}} \equiv \hat{P}_{(k_1,\cdots,k_p)(k_{p+1},\cdots,k_{p+q})(k_{p+q+1},\cdots,k_{p+q+r})}$$

(2.7)

with the only condition that the sum of each cycle length must be equal to $N$. 

2
\[ p + q + r + \cdots = N \] 

(2.8)

(here we adopt the convention \( p \geq q \geq r \geq \cdots \)). The properties of transformation of such operators under permutation do not change the length of the cycles, and therefore all the cyclic permutation with the same values of \( p, q, r, \cdots \) are said to form a class. Obviously there are as many classes as many are the possible decomposition of \( N \) as sum of integer numbers.

From the properties of the exchange operators \( \hat{P}_{i,j,k} \) it follows that the permutation operators admit only two common eigenstates, with the eigenvalues \( \epsilon_{i,j,k} \) all equal to 1 or \(-1\). In fact, the eigenvalue equation for the exchange operators \( \hat{P}_{i,j,k} \) is

\[ \hat{P}_{i,j,k} f(1, 2, \cdots, N) = \epsilon_{i,j,k} f(1, 2, \cdots, N) \] 

(2.9)

then, from the relation

\[ \hat{P}_{i,j,k} = \hat{P}_{i,2,k} \hat{P}_{1,j} \hat{P}_{i,2,k} \hat{P}_{2,j} \hat{P}_{1,j} \] 

(2.10)

it follows

\[ \epsilon_{i,j,k} = \epsilon_{1,2} \epsilon_{2,k} \epsilon_{1,j} = \epsilon_{1,2}. \] 

(2.11)

These eigenvalues \( \epsilon_{i,j,k} \) correspond respectively to vectors of state completely symmetric or antisymmetric under the exchange of two particles, and we indicate the subspaces spanned by these vectors by \( \mathcal{H}_+ \) and \( \mathcal{H}_- \) respectively. For \( N = 2 \) the Hilbert space can be decomposed exactly as \( \mathcal{H} = \mathcal{H}_+ \oplus \mathcal{H}_- \), i.e., only symmetric or antisymmetric states are possible. For \( N > 2 \) this is no more true, and we have

\[ \mathcal{H} = \mathcal{H}_+ \oplus \mathcal{H}_- \oplus \mathcal{H}_1' \oplus \mathcal{H}_2' \oplus \cdots, \] 

(2.12)

where \( \mathcal{H}_j' \) are permutation-invariant subspaces. Contrastly to \( \mathcal{H}_+ \) and \( \mathcal{H}_- \), which have a definite symmetry and are one-dimensional representation of the permutation group (for a given set of quantum numbers \( \{1, 2, \cdots, N\} \) there exist only one possible combination which gives symmetric or antisymmetric states), the subspaces \( \mathcal{H}_j' \) do not posses a definite symmetry and have dimension greater that one. This is the reason why one usually assumes the symmetrization postulate (SP), requiring physical states to be either symmetric or antisymmetric. Nevertheless, there is no stringent reason to exclude \textit{a priori} the possibility of physical states not obeying SP, since their presence do not violate any basic principle of Quantum Mechanics. The only difference that one has to take into account is the lack of a correspondence between physical states and vectors (modulo a phase factor), since the subspaces \( \mathcal{H}_j' \) have dimension greater that one and do not admit a complete set of mutually commuting physical observables. In fact, let us imagine to have a common eigenvector \( |u\rangle \) of a complete set of operators \( \{O_i\} \) in \( \mathcal{H}_j' \). Since \( |u\rangle \) cannot be eigenvector of all the permutation operator, there must exist some permutation such that \( \hat{P}_{j_1,j_2,\cdots,j_N} |u\rangle \) is linearly independent of \( |u\rangle \), and therefore \( \mathcal{H}_j' \) must have dimension greater that one, and the set of operators \( \{O_i\} \) cannot be complete (i.e., the state of the system is not completely determined by the set of eigenvalues \( \{o_i\} \)).

In the following we work out in more detail the permutation properties for the special case \( n=3 \) [20].

\section{B. A system of 3 identical particles}

The symmetrization group \( S_3 \) is a non-abelian group of order 6, formed by the 3! cyclic permutations of the labels \( (1, 2, 3) \), which belong to three distinct classes

\[ P_{(1)(2)(3)} = I \] 

(2.13)

\[ P_{(2,3)}; \quad P_{(1,3)}; \quad P_{(1,2)} \] 

(2.14)

\[ P_{(1,2,3)} = P_{231}; \quad P_{(3,2,1)} = P_{312}. \] 

(2.15)

This group is isomorphic to the dihedral group \( D_3 \), generated by the symmetry transformation shown in Fig. 1. In fact, reflection about each axis \( (a, b, c) \) is equivalent to a two label permutation \( P_{(i,j)} \), while rotations around the center by angles \( 2\pi/3 \) and \(-2\pi/3 \), lead to cyclic permutation of all the three labels. The visualization of the group \( S_3 \) by its association to the geometrical symmetries of \( D_3 \) is very helpful since it is indeed this realization on a physical system (a molecule in our case) that we are looking for.

The permutation operators can be written explicitly in a matrix form, on the basis formed by the 3! permutations of the vector \( |1, 2, 3\rangle \). For example, by defining

\[ |1, 2, 3\rangle \equiv |1 \rangle \] 

(2.16)

\[ |1, 3, 2\rangle \equiv |2 \rangle \] 

(2.17)

\[ |2, 1, 3\rangle \equiv |3 \rangle \] 

(2.18)

\[ |2, 3, 1\rangle \equiv |4 \rangle \] 

(2.19)

\[ |3, 1, 2\rangle \equiv |5 \rangle \] 

(2.20)

\[ |3, 2, 1\rangle \equiv |6 \rangle \] 

(2.21)

we obtain

\[ P_{(1,2,3)} = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \end{pmatrix}, \] 

(2.22)

and

\[ P_{(3,2,1)} = \begin{pmatrix} 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \end{pmatrix}. \] 

(2.23)
This matrix representation of the group $S_3$ can be reduced, since it must contain a number of irreducible representations equal to the number $n_e$ of distinct classes ($n_e = 3$). Moreover, since this is the so called regular representation, each irreducible representation must appear a number of times equal to its dimensionality. From general results \[20\] we know that these representations are the symmetric and antisymmetric ones (which are 1-dimensional), and that there must be also a 2-dimensional representation occurring two times. A formal way to systematically reduce the regular representation of $S_n$ into its irreducible components would be by using the Young diagrams \[20\]. Here we work out the $S_3$ case with more heuristic arguments, as follows.

First of all, we can define the operators $\mathcal{S}$ and $\mathcal{A}$, which are respectively the projectors on the subspaces $\mathcal{H}_+$ and $\mathcal{H}_-$

$$\mathcal{S} = \left[I + P_{213} + P_{312} + P_{321} + P_{231}\right]/6 \quad (2.24)$$

$$\mathcal{A} = \left[I - P_{213} - P_{312} - P_{321} + P_{231}\right]/6 \quad (2.25)$$

Each of them has therefore only one eigenvector associated to a non-zero eigenvalue, which are respectively

$$\lambda_\pm = e^{\mp i\pi}$$

and are the standard symmetric and antisymmetric states.

Then, in order to generate the two 2-dimensional irreducible representations of $\mathcal{H}'$, we can try to diagonalize the permutation operators $P_{(1,2,3)}$ and $P_{(3,2,1)}$. The eigenvectors of the former, and their corresponding eigenvalues $\lambda$, are

$$\begin{align*}
|v_1\rangle &\equiv \lambda_-|2\rangle + \lambda_+|3\rangle + |6\rangle; \quad \lambda_- = e^{-2\pi i/3} \\
|v_2\rangle &\equiv \lambda_+|1\rangle + \lambda_-|4\rangle + |5\rangle
\end{align*} \quad (2.28)$$

The other cyclic permutation, $P_{(3,2,1)}$, has the same eigenvectors, with the eigenvalues exchanged.

By looking at the behavior of such states under the exchange of two particles, it is easy to find out that the two invariant subspaces $\mathcal{H}'_1$ and $\mathcal{H}'_2$ are generated respectively by $\{v_1, v_4\}$ and $\{v_2, v_3\}$. Therefore, the effect of a generic exchange is a rotation of the vectors in $\mathcal{H}'_j$, with a change of the eigenvalues of $P_{(1,2,3)}$ and $P_{(3,2,1)}$. For example, the action of $P_{(2,3)}$ on $v_1$ gives

$$(2.29)$$

The resulting vector is $v_4$, which corresponds to a different eigenvalue of both cyclic permutations. The same result applies for the other two exchanges.

In the next Section we investigate the consequences of these properties of the cyclic permutations for the specific case of three nuclei bound in a rigid molecule, and the possible physical implication of the existence of these states not obeying SP.

### III. SYMMETRY-FORBIDDEN STATES IN SYMMETRICAL 3-NUCLEI MOLECULES

#### A. Three spin-0 identical nuclei

The prototypal molecule that we want to consider is composed by three identical spin-zero nuclei disposed at the vertices of an equilatera triangle, as sketched in Fig. 4, whose symmetries belong to the dihedral group $D_3$. Anyway, the discussion below can be extended to any symmetrical molecule with additional nuclei in the plane (point group $D_{3h}$).

Within the Born-Oppenheimer approximation, the total wave function can be decomposed in the usual way as

$$\Psi = \Psi_e\Psi_n\Psi_v\Psi_r,$$  \quad (3.1)

where the partial wave functions are respectively the electronic, nuclear spin, vibrational and rotational components. To simplify our description, we can assume the molecule to be in the ground electronic and vibrational state, with species $^1\Sigma$ (which is the most common case), or, in other words, we assume the total electronic spin, electronic angular momentum and vibrational angular momentum to be zero. Therefore, the electronic and vibrational wave functions $\Psi_e$ and $\Psi_v$ are completely symmetrical under any permutations of the labels of the nuclei. In the case of spin-zero nuclei also the nuclear spin wave-function $\Psi_n$ is symmetric under permutations, and therefore we must consider the symmetry of the rotational wave-function alone.

For this purpose, we briefly recall the main properties of the rotational states of such a molecule, which are eigenstates of the rigid rotational Hamiltonian

$$H = B(J/\hbar)^2 - (B - C)(K/\hbar)^2,$$  \quad (3.2)

where $B$ and $C$ are the two rotational constants, $J$ is the total angular momentum and $K$ is its projection on the
three-fold symmetry axis perpendicular to the molecule’s plane. The eigenvalues of the Hamiltonian are of the form

\[ E(J, K) = BJ(J + 1) - (B - C)K^2, \]

with \( K = -J, -J + 1, \ldots, J \), and are strictly degenerate in the sign of \( K \) as far as the molecule is symmetric, even if non-rigidly and perturbations are considered (the degeneracy accounts for the undistinguishability of the two orientations of \( K \) with respect to the molecular axis). The eigenfunctions are somewhat complicated functions of \( J, K \), and of the Eulerian angles \( ^2 \); they also depend parametrically on the equilibrium positions of the three nuclei in the molecular potential. Here we are interested in their transformation properties under a generic rotation of the molecule. The general rule for such transformations is the usual

\[ \Psi_r \rightarrow \Psi_r e^{i\alpha u_\alpha \cdot J}, \]

where \( \alpha \) is the angle of rotation and \( u_\alpha \) is the versor of the plane containing \( \alpha \). To find the symmetry character of the rotational states, we want to compare this transformation rule to those associated to the permutations of particles. For such purpose we write the generic rotational states in a formal way as a function of the coordinates of the three minima in the molecular potential

\[ |x_1, x_2, x_3\rangle. \]

These states are defined in the 6-dimensional Hilbert space defined in the previous Section. We note that a permutation of the quantum labels corresponds to a classical permutation of the nuclei’s mean positions, and therefore all the permutations are equivalent to rotations of the molecule.

We start by considering rotations in the plane of the molecule by angles \( \theta = \pi 
\) with \( \epsilon = \pm 1 \), which are equivalent to the cyclic permutations \( P_{(1,2,3)} \), \( P_{(3,2,1)} \). Since the effect on the molecular wave function of these rotations must be the same of such cyclic permutations, we can compare the general transformation rules under rotations and under permutations. For the formers, the appropriate phase shift is given by

\[ \Psi_r \rightarrow \Psi_r \exp i2\pi K/3, \]

since the rotation is in the molecule’s plane, while for the permutations we have

\[ \Psi_r \rightarrow \Psi_r, \quad \text{and} \quad \Psi_r \rightarrow \Psi_r \exp i2\pi/3, \]

respectively for states in \( \mathcal{H}_+ \) and \( \mathcal{H}_- \), and in \( \mathcal{H}' \). Therefore, a state with \( K = 3q \), with \( q \) integer, can be defined in \( \mathcal{H}_+ \) or \( \mathcal{H}_- \), while states with \( K = 3q \pm 1 \) can be defined only in \( \mathcal{H}' \).

For the special case of a rotational state with \( K = 0 \), we can consider also rotations about any of the three symmetry axes in the plane of the molecule by angles \( \phi = \pi \). Such rotations are equivalent to the three exchanges \( P_{(1,2)}, P_{(2,3)}, \) and \( P_{(1,3)} \), and also the correspondent phase shifts in the wave function must be identical. This class of rotations transform the wave function as

\[ \Psi_r \rightarrow \Psi_r \exp i\epsilon\pi J, \]

according to Eq. (6.4), since the angular momentum \( J \) lays in the molecule’s plane. The exchanges are instead characterized by

\[ \Psi_r \rightarrow \Psi_r, \quad \text{and} \quad \Psi_r \rightarrow \Psi_r \exp i\pi, \]

for states belonging respectively to \( \mathcal{H}_+ \) and \( \mathcal{H}_- \). As a result, the even-\( J \) states belong to \( \mathcal{H}_+ \), and the odd-\( J \) ones to \( \mathcal{H}_- \), as summarized in Tab. 1.

From the results obtained above, it appears that all the rotational states with \( K = 3q \pm 1 \) are strictly forbidden by the SP, which requires any physical state to be defined in \( \mathcal{H}_+ \) or \( \mathcal{H}_- \). Moreover, the odd-\( J \) states with \( K = 0 \) are forbidden by the spin-statistics, since the identical nuclei are spin-0 particles. The latter case is very similar to that of symmetrical molecules with two identical nuclei \( ^2 \). These consequences of both the SP and the spin statistics are well known in the field of molecular spectroscopy \( ^2 \), since they lead to the absence of more than two thirds of the rotational states in molecules with the proper symmetry, as confirmed by the experimental investigation performed so far.

We now discuss a property of the SP-forbidden states, which can be defined in the unsymmetrical subspace \( \mathcal{H}' \). Specifically, the states with \( K = 3q \pm 1 \) could be described by the vectors \( v_1, v_2 \), while the ones with \( K = 3q + 1 \) by the vectors \( v_3, v_4 \) to preserve the equality of the phase shifts reported in Eq. (3.6) and Eq. (3.7). As we noted, such pairs of vectors do not define invariant subspaces, and therefore the physical states have to be defined in the two invariant subspaces \( \mathcal{H}_1' \) and \( \mathcal{H}_2' \). Although in each of these subspaces the sign of the rotational phase shift is not defined (see Eq. (2.29), also the sign of \( K \) is not a physical observable, due to the degeneracy of the states with \( \pm K \). In other words, even if in \( \mathcal{H}' \) it is not possible to define a complete set of operators due to its multi-dimensionality, and in particular the sign of \( K \) is undefined, no paradox arises, since we have no means to measure such a sign.

B. Three spin-1/2 identical nuclei

In case of a molecule containing three identical nuclei with non-zero spin, we should consider also the influence of the nuclear spin wave function; in the following we will discuss the special case of spin 1/2. Since the spin is non-zero, we can now define a non-trivial Hilbert space for the spin, in the same way we defined it for the spatial coordinates. The total Hilbert space will be the direct product of the rotational and spin spaces.
\[ \mathcal{H} = \mathcal{H}_S \otimes \mathcal{H}_R. \]  

(3.10)

The general properties of the Hilbert space can be easily found, considered the discrete nature of the quantum labels associated to each particle. The generic three-particles state is now defined as

\[ |S_{z1}, S_{z2}, S_{z3}\rangle, \]  

(3.11)

and there are two states with total spin \( I=1/2 \) and one with \( I=3/2 \) (two doublet and one quartet). Using the formalism of Section II it is possible to assign the quartet state to the symmetrical subspace \( \mathcal{H}_+ \), and the two doublet to the unsymmetrical \( \mathcal{H}' \). We note that is not possible to build non-vanishing states completely antisymmetric under permutations of more than two spin-1/2 particles, since each quantum label can assume only two values.

Even in absence of an electronic or vibrational angular momentum, the nuclear spin can couple to the rotational angular momentum and give rise to a very small hyperfine splitting of the rotational states. The molecular states will therefore be eigenstates of the total angular momentum \( \mathbf{F}=\mathbf{J}+\mathbf{I} \). We want now to assign each molecular state to a particular subspace of the overall Hilbert space, as we did in the previous case. For such purpose we have to decompose the representation of the \( S_3 \) group on the direct product Hilbert space \( \mathcal{H}_S \otimes \mathcal{H}_R \), into irreducible representations. By using general rules we easily obtain the decomposition shown in Tab. I.

It is then straightforward to evaluate the appropriate Hilbert subspace for the overall rotational and nuclear spin states, using the associations of Tab. I; the results are reported in Tab. II. If the hyperfine splitting of the rotational states is not resolved, as it is usually the case, the states with \( K \neq 0 \) are no more completely forbidden by the SP, while the even-\( J \) states with \( K=0 \) are forbidden by both the SP and the spin-statistics. Specifically, the states defined in \( \mathcal{H}_+ \) will have \( I=3/2 \), and the ones in \( \mathcal{H}' \) \( I=1/2 \). As a consequence of the multidimensionality of \( \mathcal{H}' \), it is impossible to distinguish between the two doublet states, but this is not a problem, since they are rigorously degenerate. In fact the invariant subspaces of \( \mathcal{H}' \) are eigenstates of \( I_z \), and therefore also in presence of a magnetic field there is no fundamental principle other than the SP to forbid the existence of these unsymmetrical states.

We conclude by noting that in the case of a nuclear spin larger than 1/2 it is possible to build also antisymmetrical spin states in \( \mathcal{H}_- \), and therefore none of the rotational states with \( K=0 \) is forbidden.

C. Non-planar symmetrical molecules

We now extend the discussion to non-planar symmetrical molecules containing three spin-0 or spin-1/2 identical nuclei (point group \( C_{3v} \)): the molecule has additional non-identical nuclei out of the plane containing the identical nuclei. The main difference from the planar case stands in the transformation rule of the \( K=0 \) rotational states under rotations about a symmetry axis in the plane of the three identical nuclei. These rotations, by angles \( \phi=s\pi \), are not identical to permutations of two identical nuclei, as it was for a planar molecule, since also the additional nuclei out of the plane has rotated. On the other hand, the combination of such a rotation with an inversion of the coordinates of all the nuclei with respect to the origin cannot be distinguished from a permutation of two nuclei.

The properties of the rotational states under space inversion are well known in the field of molecular spectroscopy, and here we give only the main result. If the non-rigidity of the molecule is taken into account, each rotational state is split into two states with definite symmetry under inversion (\( s \)- and \( a \)-species, respectively symmetric and antisymmetric under inversion). The splitting of the degeneracy of these pairs of states is indicated as inversion splitting. The analogous of the transformation rule of Eq. (3.8) for the rotation plus inversion is therefore

\[ \Psi_r \rightarrow \pm \Psi_r \exp i\epsilon\pi J, \]  

(3.12)

where the positive (negative) sign refer to the \( s \)-species (\( a \)-species). If we compare this rule with the one for the exchange of two particles (Eq. (3.9)) we can assign each rotational state to the proper symmetry class, as summarized in Tab. II for the cases of spin-0 and spin-1/2.

In the last Section we will indicate one molecular species in which the inversion splitting is sufficiently large to resolve the states forbidden by the SP from those allowed.

IV. TESTING SMALL SYMMETRY VIOLATIONS

As we noted above, those rotational states forbidden by the SP can be defined consistently in the unsymmetrical subspace \( \mathcal{H}' \), since they are not violating any basic principle of Quantum Mechanics. The discussion can be extended to particular classes of rotational sub-states in excited vibrational and electronic states; due to the different symmetry of the vibrational and electronic wave functions, different classes of \( K \)-levels and \( J \)-levels can be forbidden by the SP. In any case, electromagnetic transitions between rotational levels are allowed only if the involved states belong to the same symmetry type, in accordance with the superselection rule.

Therefore, a violation of the SP can be thought of only in terms of the appearance of a population of nuclei identical between themselves, whose quantum states belong to \( \mathcal{H}' \), and whose properties (mass, spin, charge) are the same as those of the normal nuclei. The presence of a non-zero population in SP-forbidden rotational states of the molecules formed by such nuclei could be detected by
exciting electromagnetic transitions towards other forbidden states, in the same way it was done in previous experiments for testing the statistics. For a matter of sensitivity, the experimental investigation should focus on states completely forbidden by the SP alone, or by both the SP and the spin-statistics, since we expect the violation, if present, to be very small. Therefore, the most interesting states to be probed in both \( D_{3h} \) and \( C_{3v} \) molecules are those with \( K=3q \pm 1 \) in the case of \( S=0 \), and those with \( K=0 \) in the case of \( S=1/2 \).

We note also that all the statements above would not lose validity in case of breakdown of the Born-Oppenheimer approximation. Indeed, the symmetry character of the particles under permutation can only be assigned to a single class (i.e. Hilbert subspace), as stated by the super-selection rule, and no coherent superposition is allowed [17]. Therefore, if the total wave function appears to be correctly described as symmetrical (unsymmetrical) in the frame of the Born-Oppenheimer approximation, it would be so for any degree of violation of the approximation itself. The same argument applies in case of presence of external perturbations, such as electric or magnetic fields: even if they can change the molecular wave function to a large extent in a continuous way, the symmetry character of the wave function will be locked to a single class.

V. PROPOSAL FOR A HIGH-SENSITIVITY TEST OF THE SYMMETRY ON OXYGEN NUCLEI AND PROTONS

A simple tool to investigate for possible violations of the SP would be high sensitivity spectroscopy of a thermal sample of gas, in search for a non-zero absorption of light by symmetry-violating molecules, as performed in previous experiments on the spin-statistics. It is possible to define a few general criteria to choose the proper molecule for such an experimental search. The first important parameter is the weight of the molecule, which determines the spacing between adjacent rotational transitions (the rotational constants \( B \) and \( C \) are inversely proportional to the mass), and therefore also the capability of resolving the forbidden transitions from the allowed ones [24]. This point is very important, since in non-linear molecules the number of transitions which can possibly interfere in the detection of SP-violations is increased with respect to linear molecules, due to the increased molteplicity of rotational states. Secondly, in order to have a high sensitivity in detecting a violation of the SP, one should probe strong transitions starting from low-laying rotational states in the ground electronic and vibrational state, which have the largest occupation probability. As usual, in this kind of molecules the strong electronic transitions are confined to the UV, where laser sources are not easily available, and therefore one should rely on the fundamental vibrational transitions in the infrared, which are somewhat weaker. It is therefore important to find a near coincidence between a vibrational band and the emission of a coherent laser source suitable for high sensitivity spectroscopy. The quantum-cascade semiconductor lasers are particularly interesting from this point of view, since they can be designed to emit almost everywhere in the mid-infrared, they are widely tunable and have low-noise characteristics [24].

In the case of spin-0 nuclei, the lightest molecule with the proper symmetry is the plane \( SO_3 \) (group \( D_{3h} \)), whose vibrational energies [24] are reported in Tab. 1. In principle the sensitivity for detection of SP-violating transitions can be expected to be comparable to those obtained in previous experiments on molecular systems. It could possibly be reduced by increased experimental difficulties (for example, \( SO_3 \) is not chemically stable in presence of oxygen, and therefore may not be easy to have the proper pressure and cell volume to optimize the sensitivity) or more fundamental limitations, such as the presence of weak hot-transitions close to the SP-forbidden ones.

An alternative approach could be to perform the spectroscopic investigation on a supersonic beam of \( SO_3 \), instead of a thermal sample. With this technique, the problems connected with the high reactivity of \( SO_3 \) could possibly be solved, while the reduction in density of the sample could be compensated by the reduction of the rotational temperature and by an increase of the detection sensitivity. In addition, one would benefit from the accompanying increase in resolution, for a better identification of the detected spectrum of transitions.

As for the case of spin-1/2 nuclei, it is possible to find a relatively light plane molecule, \( BH_3 \) (group \( D_{3h} \)), on which to search violations of the SP and of the spin-statistics for \( K=0 \) rotational states. As we mentioned, the same symmetry properties can be found also for the corresponding rotational states of non-planar symmetrical molecules (group \( C_{3v} \)) with inversion splitting. One of the most interesting species of this kind is \( NH_3 \), which is stable and particularly light, and has very strong vibrational absorption bands in the infrared spectral region covered by semiconductor lasers. Moreover, its spectrum has been the subject of extensive investigation, and therefore the assignment of observed lines can be performed in a relatively easy way. In addition, it is characterized by a very large inversion splitting of the rotational spectrum, and therefore the forbidden lines can be easily distinguished from the allowed ones. For such molecules, which are composed by spin-1/2 nuclei, we noted that for the \( K=0 \) states different hyperfine components are forbidden by the SP and by the spin-statistics. Since the hyperfine slitting of the rotational levels is usually negligible (at least for \( \Sigma \) electronic states [22]), we can expect to resolve the two classes of substates only thanks to Zeeman effects in strong magnetic fields.

To conclude, we note that in the case of \( BH_3 \) or \( NH_3 \), one would be testing the SP and the spin-statistics for protons. Such an experimental test would be particularly interesting to compare the present bound for violation of
the statistics for composed nucleons \[3\] to a corresponding bound for fundamental nucleons, also in view of the recent theoretical predictions \[15\].

VI. CONCLUSIONS

We have shown how to define consistently particular classes of rotational levels of symmetrical molecules containing three identical nuclei, by allowing for violations of the symmetrization postulate. This violation, if existing, must be small, according to the results of the past experimental observations. However, it is possible to look with high sensitivity for the presence of tiny population in SP-forbidden states, using spectroscopic tools in a scheme similar to those of previous experiments on O$_2$ and CO$_2$. If we allow for the presence of molecules composed by SP-violating nuclei in a sample of gas, which are identical to the normal molecules in all but the symmetry, then such a measurement can be interpreted as a test of the SP. This kind of experiment would represent a substantial improvement with respect to the past investigations on O$_2$ and CO$_2$. The latter species are particularly interesting, since they represent systems on which to test the SP for fundamental nucleons.
