Single-component emitters with stable and bright warm white-light emission are highly desirable for high-efficiency warm white light-emitting diodes (warm-WLEDs), however, materials with such luminescence properties are extremely rare. Low-dimensional lead (Pb) halide perovskites can achieve warm white photoluminescence (PL), yet they suffer from low stability and PL quantum yield (PLQY). While Pb-free air-stable perovskites such as Cs₂AgInCl₆ emit desirable warm white light, sophisticated doping strategies are typically required to increase their PL intensity. Moreover, the use of rare metal-bearing compounds along with the typically required vacuum-based thin-film processing may greatly increase their production cost. Herein, organic–inorganic hybrid cuprous (Cu⁺)-based metal halide MA₂CuCl₃ (MA = CH₃NH₃⁺) that meets the requirements of i) nontoxicity, ii) high PLQY, and iii) dopant-free is presented. Both single crystals and thin films of MA₂CuCl₃ can be facilely prepared by a low-cost solution method, which demonstrate bright warm white-light emission with intrinsically high PLQYs of 90–97%. Prototype electroluminescence devices and down-conversion LEDs are fabricated with MA₂CuCl₃ thin films and single crystals, respectively, which show bright luminescence with decent efficiencies and operational stability. These findings suggest that MA₂CuCl₃ has a great potential for the single-component indoor lighting and display applications.

1. Introduction

High-performance warm white-light-emitting diodes (warm-WLEDs) are highly required for the widespread use of solid-state lighting especially indoors.¹,² There are currently three main methods for producing warm-WLEDs: first, coating yellow and red phosphors on blue LEDs; second, coating a mixture of red, green, and blue (RGB) phosphors on UV LEDs; third, directly mixing RGB LEDs. However, each of these three technologies has its own shortcomings, such as the poor color rendition, low emission efficiency, and discontinuity in the visible light spectrum.³,⁴ Development of new single-component warm white light-emissive phosphors with high photoluminescence quantum yield (PLQY) and color stability bears great significance for high-performance warm-WLEDs: On the one hand, single-component warm white phosphors do not rely on additional red phosphors to adjust their correlated color temperature (CCT); meanwhile, because of the unique broad-spectrum luminescence characteristics, warm white phosphors can solve the problem of discontinuity in the visible light spectrum of RGB LEDs. On the other hand, single materials with efficient and stable warm white-light emission can be directly fabricated into electrically driven warm-WLEDs, which ultimately addresses concerns of the aforementioned down-conversion applications.²,⁵–⁷

However, there are very few compounds of the nonrare earth ions which have high-efficiency warm white emission. Highly distorted low-dimensional lead (Pb)-based perovskites such as 2D α-(DMEN)PbBr₄ (DMEN = 2-(dimethylamino)ethylamine) are...
found to be capable of emitting warm white light. However, the inherent toxicity of Pb will hamper their practical commercialization; Pb-free double perovskites such as 3D Cs$_x$AgInCl$_3$ and some pure In-based 0D perovskites (e.g., Cs$_3$InCl$_5$·H$_2$O) are also found to possess warm white fluorescence, but optical properties of these halide derivatives are highly sensitive to trace element doping, which brings difficulty to large-scale production and reproducibility. Besides, indium belongs to costly rare earth element, which hampers widespread employment of these materials. [6,9–11] 0D tin (Sn)-halide perovskites are also commonly studied as potential warm white-light emitters, yet significant challenges remain as Sn$_{2+}$ can be easily oxidized to Sn$_{4+}$ upon air exposure. [12,13] In recent years, cuprous (Cu$^+$)-based metal halides have received extensive attention in the research field of luminescence because they are nontoxic, earth-abundant, and intrinsically highly emissive without the aid of any sophisticated doping. For example, A$_2$CuX$_3$ (A = K, Rb; X = Cl, Br), MA$_2$CuBr$_6$ (MA = CH$_3$NH$_3^+$), (TBA)CuX$_2$ (TBA = tetrabutylammonium cation), and Cs$_3$CuX$_5$ (X = Cl, Br, I) can be facilely prepared via solution synthesis, which show near-UV to green emission with near-unity PLQYs. [14–20] In addition to these narrowband emissions, the broadband emission which is a prerequisite for yielding warm white light can be also achieved with these Cu$^+$-based compositions, such as CsCu$_2$I$_3$·[KC$_2$]$_3$·[Cu$_4$I$_6$] (C = 12-crown-4 ether), [(C$_6$H$_5$)$_2$Ni]Cu$_2$I$_4$, (Gua)$_2$Cu$_2$I$_4$ (Gua = guanidine), etc. [21–25] However, despite the broadband emission, very few of these materials exhibit the desirable warm white light which features CCT value of around 2700 to 4000 K. Besides, one can see that most of these Cu$^+$-based broadband emissive halides are iodide compounds, which severely restricts the possible adjustment of the spectral response through halide composition. The aforementioned facts highlight the urgency to develop new single-component phosphors which have merits of broadband warm white-light emission, low-cost processing, non-toxicity, high PLQY (without extrinsic doping), and high color stability.

In this work, an efficient ultrabroad-band solid warm white-light emission from dopant-free Cl-based metal halide MA$_2$CuCl$_3$ is first reported. MA$_2$CuCl$_3$ can be facilely prepared in the form of centimeter-sized single crystals, which show desirable PL emission in the visible range from 450 to 800 nm, CCT of 3607 K, and an intrinsically high PLQY of 97%. Spectroscopic characterizations reveal an exceptionally strong exciton–photon coupling in MA$_2$CuCl$_3$, which surpasses most other Cu$^+$-based metal halides. Theoretical calculations further unveil a unique electronic structure for MA$_2$CuCl$_3$, which features highly localized holes and spatially isolated excitons. These correlate well with their high PLQYs and long radiative lifetimes. To better utilize the intrinsically high PLQYs of MA$_2$CuCl$_3$ and to enhance their prospects and potential in warm-WLEDs, we further devised a novel methanol-based approach to deposit large-scale and uniform MA$_2$CuCl$_3$ thin films, which show high PLQY of 90%. Compared to traditional methods that employ coordinating solvents, such as N,N-dimethylformamide (DMF) and dimethylsulfoxide (DMSO), the methanol-produced thin films are of higher quality in terms of continuity and compactness. The ensuing electrically driven LEDs based on MA$_2$CuCl$_3$ thin films achieve a maximum luminance of 54 cd m$^{-2}$ and a maximum external quantum efficiency (EQE) of 0.035%, which is comparable to that of state-of-the-art warm white-emissive Pb-free perovskite LEDs; UV-pump LEDs based on MA$_2$CuCl$_3$ solids show a brightness up to 5500 cd m$^{-2}$ and a maximum EQE of 0.6%, which retain >90% of the initial luminance after 45 min of operation in ambient air. Our findings unambiguously show that the hybrid metal halide MA$_2$CuCl$_3$ holds great potential to be used as a new kind of single-component light emitter in warm-WLEDs.

2. Results and Discussion

We have succeeded in identifying two synthetic routes toward MA$_2$CuCl$_3$. The first approach involves an inverse temperature crystallization process, which yields single crystals with centimeter-scale length. Briefly, powder mixtures containing MACl and CuCl were dissolved in solvent mixture of concentrated hydrochloric acid and phosphinic acid (H$_3$PO$_2$) at 130 °C and then slowly cooled to 10 °C in a thermostat at a cooling rate of 3 °C min$^{-1}$. After ≈48 h of growth, the crystals were taken out of the solution, washed by hexane, and dried with a N$_2$ gun (more experimental details can be found in the Supporting Information). Single-crystal X-ray diffraction (SCXRD) analyses performed on the as-grown crystals suggest a specific chemical composition of MA$_2$CuCl$_3$, which crystallizes in the monoclinic P2/n space group and features a 0D structure at the molecular level. In this material, each [Cu$_2$Cl$_4$]$^{2-}$ dimer is spatially separated by wide band gap organic framework of MA$^+$. (See Figure 1a; Tables S1–S6 of the Supporting Information). Figure 1b shows the simulated powder XRD pattern for MA$_2$CuCl$_3$. MA$_2$CuCl$_3$ forms single crystals that present as 0.5 cm wide and 1.8 cm long rod (Figure 1c), whose morphology conforms to the underlying symmetry of the crystal lattice. It is noted that size of the obtained single crystals can be increased even further by using a bigger scintillation vial, significantly larger than most of the other Pb-free perovskites. [25–28] The large-scale uniform rod morphology lays the foundation for the design of centimeter-level single-crystal devices. [28,29] It is important to note that the successful application of this method for crystallization depends on the use of H$_3$PO$_2$, which was added to prevent the oxidation of Cu$^+$ [37] otherwise nonluminescent Cu$^{2+}$-contained compounds can be produced (Figure S1, Supporting Information). Similarly, we have also prepared Br-based single crystals, MA$_2$CuBr$_3$, which emit bright green light with the addition of H$_3$PO$_2$ (Figure S2, Supporting Information).

The inductively coupled plasma-mass spectrometry measured for the obtained crystals confirms the presence of Cu and Cl elements in near stoichiometric ratio of 1:3. These elements are seen to be uniformly distributed in the crystals as displayed in their energy dispersive X-ray spectroscopy (EDS) elemental mapping image (Figure 1d). To confirm the presence of Cu element in its expected oxidation state, X-ray photoelectron spectroscopy (XPS) measurement was further carried out. The measured high-resolution Cu spectrum consists of a pair separated by the Cu 2p spin–orbit splitting (Figure 1e), each of which has well-resolved single component at 931.9 and 951.7 eV, respectively, exactly matches the XPS Cu 2p spectrum of the as-bought CuCl powder. These results thus verify the SCXRD analyses and confirm the absence of those undesired Cu$^{2+}$-species in the as-prepared sample. To evaluate thermal stability of the prepared crystals, thermogravimetric analysis coupled with differential scanning
Figure 1. a) Crystal structure of MA<sub>2</sub>CuCl<sub>3</sub>, created with VESTA software based on crystallographic information obtained by X-ray single crystal structural analyses. b) Simulated powder XRD pattern for MA<sub>2</sub>CuCl<sub>3</sub>. Assignments of peaks and a CIF file are provided in the Supporting Information. c) Digital image of an early 2 cm single-crystal MA<sub>2</sub>CuCl<sub>3</sub> and d) its element distribution analysis by EDS mapping. e) XPS narrow-scan spectrum of Cu 2p and f) TG-DSC curves of MA<sub>2</sub>CuCl<sub>3</sub> single crystals.

calorimetry (TG-DSC) was carried out. It is seen from Figure 1f that the thermal degradation is multistage. The first stage begins at about 220 °C and the crystal loses 60% of its initial mass, corresponds to the degradation of MACl; the second stage which shows a mass loss of ≈36% can be attributed to the degradation of CuCl with a maximum rate near 600 °C. The above TG results agree well with the mass ratio of MACl/CuCl in MA<sub>2</sub>CuCl<sub>3</sub> crystal and prove that this material would not decompose until 220 °C. Note that the commonly studied MAPbCl<sub>3</sub> perovskite exhibits similar decomposition temperature. However, unlike MAPbCl<sub>3</sub>, we identify MA<sub>2</sub>CuCl<sub>3</sub> metal halide undergoes a melting process at ≈100 °C, as evidenced by the obvious endothermic peak in its DSC curve (Figure 1f, blue line).

Single crystals of MA<sub>2</sub>CuCl<sub>3</sub> can be also prepared by room-temperature solvent evaporation-induced crystallization strategy, following a procedure modified from a previous published synthesis. Typically, CuCl and MACl were dissolved in a mixture of DMF and H<sub>3</sub>PO<sub>2</sub>, followed by slow solvent evaporation in a vacuum drying oven at room temperature (more experimental details can be found in the Supporting Information). XRD measurements performed on hand-ground powders confirm the success of formation of monoclinic-phase MA<sub>2</sub>CuCl<sub>3</sub> (Figure S3, Supporting Information). However, most of the obtained crystalline grains have crystal sizes less than 1 mm, inferior than those obtained by inverse temperature crystallization method.

The as-synthesized centimeter-sized crystals are of sufficient quality and macroscopic dimensions to enable a detailed investigation of their optical properties, which were first investigated by UV-vis absorption and PL spectra. Figure 2a shows that the MA<sub>2</sub>CuCl<sub>3</sub> single crystals lack a clear absorption edge in its UV-vis spectrum, a strong sign that the crystals contain a certain number of sub-band-gap states which lie below its conduction band edge. The slope of this exponential part of the curve is the so-called Urbach energy (E<sub>U</sub>). A large E<sub>U</sub> reflects the semiconductors suffer from impurities, inherent structural disorders, and/or electron–phonon interaction in the absorption process. E<sub>U</sub> value of the MA<sub>2</sub>CuCl<sub>3</sub> single crystals was obtained by fitting their absorption coefficient α(E) versus photon energy E at a given temperature T (see inset of Figure 2a). According to Urbach rule, α(E) follows the relation:

\[
\alpha(E) = \alpha_0 \exp \left[ \frac{\sigma(T) (E - E_0)}{k_B T} \right]
\]

where \( \alpha_0 \) and \( E_0 \) are the characteristic parameters of the material, \( \sigma(T) \) is the steepness parameter and \( K_B \) is the Boltzmann constant. The quantity \( K_B T/\sigma(T) \), which is the width of the exponential tail, is \( E_U \). By fitting the band tail state, we obtained \( E_U \) value = 84 meV, significantly larger than most of Pb-based bulk perovskites (≈15 meV). Such large \( E_U \) can be attributed to the effect of strong electron–phonon interaction in MA<sub>2</sub>CuCl<sub>3</sub>, which induces elastic structural distortion and creates transient electronic states upon photoexcitation. The strength of electron–phonon coupling in MA<sub>2</sub>CuCl<sub>3</sub> will be studied in the following text using temperature-dependent PL measurement. The PL excitation (PLE) spectrum shown in Figure S4 in the Supporting Information...
Information indicates that the MA$_2$CuCl$_3$ single crystals have an optimal excitation wavelength around 310 nm. Under 310 nm UV excitation, bulk crystals of MA$_2$CuCl$_3$ exhibited broadband warm white emission from 450 to 800 nm and had large Stokes shift of 200 nm, indicating negligible overlap between absorption and emission spectra (Figure 2b). This is of great importance for luminescent materials as one would expect minimum loss of light emission in thin films unlike excitonic or band edge emission.[39] According to the Commission Internationale de l’Eclairage (CIE) 1931 standard color matching functions, the emitted light can be demonstrated by ($x$, $y$) chromaticity coordinates (0.44, 0.52) and a CCT of around 3607 K in the warm white region (Figure S5, Supporting Information). Remarkably, PLQY of these dopant-free MA$_2$CuCl$_3$ single crystals reaches as high as 97%, making them one of the most efficient warm white-light emitters reported to date. Table S7 in the Supporting Information summarizes and compares optical properties of some recently developed Cu$^{+}$-based hybrids, which visually showcases the uniqueness of our MA$_2$CuCl$_3$ as a warm white-light-emitting material. The high PLQY implies that the carrier recombination in such materials is dominated by radiative process and the defect-related nonradiative recombination is negligible. This also supports our assumption that the large $E_i$ of MA$_2$CuCl$_3$ originates from its strong electron–phonon interaction, rather than impurities or inherent structural disorders because the latter two scenarios would usually introduce nonradiative recombination centers that lower PLQY. To shed more light on how carriers in MA$_2$CuCl$_3$ crystals recombine through radiative process, time-resolved PL (TRPL) measurements were conducted. Figure 2c shows the typical TRPL curve for MA$_2$CuCl$_3$ single crystals monitoring the emission peak at 567 nm. A good fit to the data was obtained by using a mono-exponential decay function with lifetime constant of 50.45 $\mu$s. This result points to a single recombination channel in MA$_2$CuCl$_3$, which is in good line with their high PLQYs. It is noteworthy that PL lifetime of the MA$_2$CuCl$_3$ single crystals is much longer than most of the previously reported Pb-free and Pb-based perovskites whose PL lifetimes at room temperature range from tens of nanoseconds to several microseconds.[6,40–42] Such long radiative lifetime observed in MA$_2$CuCl$_3$ crystals, as we will discuss later, can be associated with their unique crystal structure, which spatially separates photo-excited electrons and holes, giving rise to prolonged exciton lifetime.

To probe into the underlying mechanism of the extraordinary broadband emission of MA$_2$CuCl$_3$ single crystals, we then examined their emission wavelength-dependent PLE spectra and excitation wavelength-dependent PL spectra. It was found that both PLE and PL spectra exhibit identical shapes at various emission (from 500 to 660 nm) and excitation wavelengths (from 240 to 320 nm) (Figures S6 and S7, Supporting Information), indicating that the broadband emission originates from the relaxation of the same excited states and rules out the possibility of ion luminescence from Cu$^{+}$.[15,43,44] It is noteworthy that the presence of permanent defect states in semiconductors could also contribute to broadband emission. However, because permanent defect recombination lifetime and concentration are finite, their
PL should be saturated at high excitation intensity.\textsuperscript{[40,45]} To examine this, Figure S8 in the Supporting Information records the power-dependent PL intensity of the MA\textsubscript{2}CuCl\textsubscript{3} single crystals at room temperature. Linear relationship between the excited power and the intensity of PL peak was observed in the range of 2.2–10.5 mJ, thereby the possibility of permanent defects emission in MA\textsubscript{2}CuCl\textsubscript{3} could be also excluded.

The distinct features, such as the broadband emission with high PLQY, large Stokes shift, and long excitonic lifetime, strongly suggest a self-trapped exciton (STE) emission in MA\textsubscript{2}CuCl\textsubscript{3}. STEs are those photo-excited electron–hole pairs whose coupling with lattice is strong enough to cause elastic distortion in the lattice surrounding them. As a result, transient, light-induced trap states formed below the conduction band, affording a broad emission with a large Stokes shift.\textsuperscript{[46–48]} Recently, several other families of In\textsuperscript{1+}, Cu\textsuperscript{2+}-based halides and layered Sn, Pb halide perovskites were reported to exhibit the STE-related emission.\textsuperscript{[47,48–52]} Interestingly, they all feature a strong electron–phonon coupling which results from their high structural distortion. To study the electron–phonon coupling in our MA\textsubscript{2}CuCl\textsubscript{3} single crystals, Huang-Rhys factor (S), which characterizes the strength of electron–phonon coupling, was extracted by using the following equation\textsuperscript{[10]}

\[
\text{FWHM} = 2.36 \sqrt{\frac{\hbar \omega_{\text{phonon}}}{\coth \left( \frac{\hbar \omega_{\text{phonon}}}{2k_B T} \right)}} \quad (2)
\]

where FWHM is the PL full-width at half-maximum and \(\hbar \omega_{\text{phonon}}\) is the phonon frequency. Figure 2d shows the temperature-dependent PL spectra of MA\textsubscript{2}CuCl\textsubscript{3}, where we see a noticeable increase in PL intensity from 80 to 340 K and then a rapid decrease above 360 K; at \(\approx 380\) K, MA\textsubscript{2}CuCl\textsubscript{3} single crystals basically lose PL. It is noteworthy that unlike those all-inorganic metal halide perovskites, such as CsCu\textsubscript{X},\textsubscript{[24]} Cs\textsubscript{2}Cu\textsubscript{X},\textsubscript{[53]} Rb\textsubscript{2}Sb\textsubscript{Cl},\textsubscript{[54]} Rb\textsubscript{2}CuBr\textsubscript{2},\textsuperscript{[55]} and RbPbI\textsubscript{4},\textsuperscript{[56]} whose PL emission consecutively decreases with increasing temperature, the positive correlation between PL emission and temperature observed in MA\textsubscript{2}CuCl\textsubscript{3} in the range of 80 to 340 K is actually quite common in these organic–inorganic hybrid compounds, including Pb- and Sn-based perovskites.\textsuperscript{[31–37]} It is suggested that because the organic framework in these materials is rigid at low temperatures, it could be difficult for the crystals to induce a structural distortion and therefore difficult to create self-trapped states. Besides, because of the low kinetic energy at low temperatures, it becomes difficult for the excitons to surmount potential barrier and to enter the self-trapped states. Another possible mechanism for the enhanced STE emission with increasing temperature could be associated with the thermally activated delayed fluorescence, which involves inverse intersystem crossing from long-lived triplet back to short-lived singlet excited states.\textsuperscript{[58–60]} As for the rapid decrease of PL intensity from 340 to 380 K, it is probably due to the thermal quenching caused by the increased thermally populated vibrational states at high temperatures.\textsuperscript{[61]} Particularly, the dramatic PL quenching at 380 K is ascribed to the phase transition of MA\textsubscript{2}CuCl\textsubscript{3} (from solid to liquid), as evidenced by DSC analysis. The FWHM data, derived from the temperature-dependent PL spectra, were plotted in Figure 2e. Unlike the trend in PL intensity, FWHM changes monotonously with the increasing temperature. It broadens significantly from 80 to 360 K, indicative of an increased optical phonon scattering with temperature.\textsuperscript{[62–64]} By fitting FWHM curve using Equation (2), the \(\hbar \omega_{\text{phonon}}\) is extracted as 20.5 ± 0.9 meV and the S factor is 41.9 ± 2.8. We note that the obtained \(\hbar \omega_{\text{phonon}}\) value matches well with the other Cu\textsuperscript{2+}-based organic–inorganic metal halides (20–40 meV), whereas S factor of MA\textsubscript{2}CuCl\textsubscript{3} is obviously higher (vs 8.46 for (TBA)CuCl\textsubscript{2}, 10.7 for MA\textsubscript{2}CuBr\textsubscript{2}, 23.2 for [(C\textsubscript{6}H\textsubscript{4}H\textsubscript{5})\textsubscript{2}Cu\textsubscript{1+}], and 11.95 for (C\textsubscript{6}H\textsubscript{5}N\textsubscript{2})Cu\textsubscript{1+}).\textsuperscript{[17,18,25,61]} This result indicates an exceptionally strong exciton–photon coupling in MA\textsubscript{2}CuCl\textsubscript{3}, which can be also corroborated by their obvious blueshift of the PL band position with increasing temperature (Figure 2f) because at higher temperatures more optical phonons would participate in the exciton–photon interaction through the short-range deformation potential.\textsuperscript{[65–67]} Such strong exciton–photon coupling paves the way for the formation of self-trapped excited states and thus the ensuing broadband emission.

To facilitate a better understanding on the electronic properties of MA\textsubscript{2}CuCl\textsubscript{3} and to unveil the physical origins of their high emission efficacy, density functional theory (DFT) calculations were performed (computational details can be found in the Supporting Information). The calculated band structure of MA\textsubscript{2}CuCl\textsubscript{3} shows a direct band gap of 3.47 eV at the Γ point (Figure 3a), which is in good agreement with the sharp absorption peak at 370 nm (\(\approx 3.35\) eV, see Figure 2a). The projected density of states (PDOS) (Figure 3b) shows that the conduction band minimum (CBM) of MA\textsubscript{2}CuCl\textsubscript{3} is composed mainly of MA\textsuperscript{+} and MA\textsuperscript{-} orbitals, whereas their valence band maximum (VBM) consists of Cu\textsuperscript{2+} orbitals, mixed with some Cl\textsuperscript{-} orbitals, as indicated by the partial charge density (Figure 3c). The VBM of MA\textsubscript{2}CuCl\textsubscript{3} features an almost flat and highly discrete band, which could be associated with the spatial isolation of [Cu\textsubscript{2}Cl\textsubscript{6}]\textsuperscript{4–} dimers by MA\textsuperscript{+} molecules, giving rise to a strong quantum confinement for the photo-excited holes in MA\textsubscript{2}CuCl\textsubscript{3}. Because photo-excited holes are highly localized in VB of the crystal, they will become less sensitive to defect states and hence contribute to enhanced radiative recombination and a single-exponential PL decay.\textsuperscript{[12,13,17,55]} Further, the analysis of the PDOS shows that the CBM of MA\textsubscript{2}CuCl\textsubscript{3} mainly consists of MA\textsuperscript{+} orbitals and the VBM mainly comes from [Cu\textsubscript{2}Cl\textsubscript{6}]\textsuperscript{4–}. Such spatial isolation of the two clusters also means that the photo-excited holes and electrons are spatially separated, leading to a delayed charge recombination and thus a prolonged PL lifetime, in good line with the TRPL results which show exceptionally long-lived excitons.

Stabilities of a luminescent material especially optical stabilities are of paramount importance for assessing their suitability for light-emitting applications. Previous temperature-dependent PL spectra of MA\textsubscript{2}CuCl\textsubscript{3} single crystals reveal a significant increase in PL intensity when the samples were heated from 80 to 340 K and then a rapid decrease above 360 K; at \(\approx 380\) K, the material basically loses PL (Figure 2d). The rapid decrease in PL intensity above 360 K is because the single crystals undergo a melting process, which is, however, reversible. Figure S9 in the Supporting Information evidences the successful recovery of PL emission upon cooling from the liquid state, as well as the crystal structure. Storage stability of the MA\textsubscript{2}CuCl\textsubscript{3} single crystals was next evaluated. Figure S10 in the Supporting Information shows that MA\textsubscript{2}CuCl\textsubscript{3} single crystals retain 50% of the initial PL intensity after exposure for 4 days in ambient air (\(\approx 30\%\) relative
humidity, RH, 300 K), while negligible change in PL intensity was observed when they are stored in an inert atmosphere (100% N₂) for over 6 months. To examine the impact of humidity on optical stability of the crystals, we have further put the sample in a high humidity atmosphere (98% RH, 300 K). PL spectra shown in Figure S11 in the Supporting Information indicate an accelerated decrease in emission intensity, which dropped below 50% of the initial value after 3 days of high humidity exposure. In addition to moisture attack, the gradual oxidation of Cu⁺ should be also held accountable for the decrease in PL intensity. Overall, the above results suggest that for optimal utilization of MA₂CuCl₃, proper encapsulation will be required. Light stability of the MA₂CuCl₃ single crystals was also assessed as it is closely related to their down-conversion phosphor applications. Figure S12 in the Supporting Information shows that under a continuous irradiation of 254 nm light, the crystal retains almost 70% of the initial intensity for over 24 h, which points to an excellent light stability.

To better utilize the intrinsically high PLQYs of MA₂CuCl₃ and to enhance their prospects and potential in LED applications, we demonstrated large-scale and uniform thin films of MA₂CuCl₃ on indium-doped tin oxide (ITO) glass. It should be noted that one of the most critical factors hindering the successful implementation of these Pb-free halides in optoelectronics is the lack of a suitable method to process them into compact thin films. Previously, warm white-emissive Cs₂AgₓNa₁₋ₓInCl₆ thin films are thermally deposited by a vacuum-based technique. Apart from the high cost and the general difficulty in precise stoichiometric control, the thermally deposited thin films are mainly consisted of those isolated nanograins with a broad size distribution. It is well known that an efficient LED device necessitates an efficient charge recombination in the emissive layer, too large a grain size or too thick an active layer will simply exacerbate problems of inefficient energy transfer, and thus deteriorate the device performance. Actually, for both Pb-based metal halides and their derivatives, the solution-based deposition technique has become the main method of choice for fabricating active layers with controllable thickness and morphology. However, solution processability of the Cs₂AgₓNa₁₋ₓInCl₆ perovskite is largely limited by the poor solubility of AgCl in most organic solvents, including DMF and DMSO. By contrast, CuCl can be readily dissolved in these coordinating solvents. We therefore turn to seek
solution-based route to MA₂CuCl₃ thin films by dissolving MACl/CuCl powders or as-prepared MA₂CuCl₃ crystals in DMF or DMSO following literature methods for Cs₃Cu₂I₅/CsCu₂I₃. However, despite the success in growing isolated MA₂CuCl₃ single crystals as described before, solution-phase deposition of high-quality thin films from such a solvent was unsuccessful and led to discontinuous films with many small cracks (see Figure S13, Supporting Information). To address this issue, we have developed a novel synthetic route, where precursor solution was prepared by dissolving the as-prepared MA₂CuCl₃ single crystals in methanol. Spin coating MA₂CuCl₃ methanol solution followed by drying at mild temperatures (<60 °C) allows the successful recovery of MA₂CuCl₃ solids on ITO substrate (more experimental details can be found in the Supporting Information). Cross-sectional and plane view scanning electron microscopy (SEM) of a typical thin-film sample revealed it to be ≈80 nm in thickness, which shows no major microscopic cracks or pinholes (Figure 3d,e). XRD pattern of the prepared thin films evidences the formation of high-purity monoclinic-phase MA₂CuCl₃ (Figure S14, Supporting Information), whose CIE color coordinates, CCT value, PL spectrum, and radiative lifetime are both like that of the single-crystal structures (Figure 3f,g and Figure S15, Supporting Information). The inset of Figure 3f presents a typical photograph of the prepared thin film, which exhibits very stable warm white-light emission under 254 nm UV light and high PLQYs approaching 90%.

The successful deposition of such highly emissive and uniform thin films thus allows great flexibility in design and optimization of electronic and optoelectronic devices based on MA₂CuCl₃ material. To demonstrate this, we first prepared prototype electroluminescence (EL) devices using a traditional structure ITO/poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS)/poly(9-vinylcarbazole) (PVK)/MA₂CuCl₃/2,2″,2‴(1,3,5-benzenetriyl)tris-(1-phenyl-1H-benzimidazole) (TPBi)/LiF/Al on quartz, shown schematically in Figure 4a, along with the band alignment in Figure 4b. Note that the valence band maximum of MA₂CuCl₃ was determined by ultraviolet photoelectron spectroscopy, shown in Figure S16 in the Supporting Information. However, despite intensive efforts including tuning MA₂CuCl₃ thin-film thickness (50–100 nm), employing 1,3,5-tri[(3-pyridyl)-phen-3-yl]benzene (TmPyPB) in place of TPBi, inserting a poly[N,N'-bis(4-butylphenyl)-N,N'-bis(phenyl)-benzidine] (Poly-TPD) or poly(9,9-dioctylfluorene-alt-N-(4-butylphenyl)-diphenylamine) (TFB) buffer layer before PVK, such device architecture cannot generate efficient EL, and due to the low luminous intensity, EL spectra of these devices cannot be displayed. The low luminous efficiency points to the presence of a significant injection barrier and/or charge injection imbalance inside the devices. We consider it possible given the extremely low valence band position of MA₂CuCl₃, which lies ≈1.5 eV below that of PVK and ≈2.1 eV with respect to PEDOT:PSS. Such large energy barrier between the hole injection layer (HIL) and emissive layer will bring difficulties in hole injection, and hence deteriorate the EL performance. To address this problem, we seek to lower valence band position of HIL by incorporating 20% 4,4′-bis(carbazol-9-yl)biphenyl (CBP) into PVK. Excitingly, the CBP-incorporated LEDs show noticeable white-light emission at bias voltage from 7 to 13 V. Figure 4c presents EL spectra of the resulting LEDs at different applied voltages. Similar to MA₂CuCl₃ thin films, the EL showed...
very broad emission with FWHM $\approx 160$ nm and the shape of the EL spectrum does not change at different applied voltages, signifying that the injected carriers are well confined in the emissive layers and the recombination zone does not change in response to different applied voltages. To our knowledge, this represents the first successful demonstration of LED application for this kind of Cu$^{+}$-based hybrid metal halide. It is noted that EL spectrum of the resulting LEDs underwent a blue shift ($\approx 60$ nm) with respect to the spectral line of MA$_2$CuCl$_3$ thin films, similar to observation of previously reported LEDs based on Cs$_2$AgIn$_{0.9}$Bi$_{0.1}$Cl$_6$ nanocrystals[73]. However, unlike Cs$_2$AgIn$_{0.9}$Bi$_{0.1}$Cl$_6$ NC-based LEDs, which exhibit an evident double-color emission, there are no notable dual emission in MA$_2$CuCl$_3$ device, ruling out parasitic emission from the neighboring charge transport layers (e.g., PVK), as well as the undesired radiative recombination through band-to-band transitions. Figure 4d presents the current–voltage–luminance ($I–V–L$) characteristics of the MA$_2$CuCl$_3$ LEDs, with the upper inset shows digital photograph of the LED driven by a 10 V bias. The emitted light shows CIE color coordinates (0.35, 0.37) and CCT value of around 5000 K. Figure 4e records CCT values of the devices under different applied voltages. The turn-on voltage (calculated at a luminance of 1 cd m$^{-2}$) required for the LED device is $\approx 6$ V. LEDs demonstrate a maximum brightness of 54 cd m$^{-2}$ and a maximum EQE of 0.035% (Figure 4f). Such EL performance is slightly lower than that of the best-performing white-emissive Cs$_2$AgIn$_{0.9}$Bi$_{0.1}$Cl$_6$-based LEDs (EQE 0.06–0.08%).[71] suggesting there still exists significant injection barrier inside our present devices, partially due to the low carrier mobility of MA$_2$CuCl$_3$ film because of the 0D structure at the molecular level. Further increase in electrical parameters of the MA$_2$CuCl$_3$-based LEDs can be expected through a more rational design of device architecture and optimization of charge-transport layers. LED performance was maintained almost constant when the devices were stored in N$_2$ atmosphere for 1 week, but dropped to $\approx 35\%$ of the initial level after 12 h of storage in ambient air (RH 30–40%) (Figure S17, Supporting Information), which is inferior to that of the pure MA$_2$CuCl$_3$ single crystals (Figure S10, Supporting Information, $T_{50} = 4$ days). We consider it to be associated with their ultra-thin thickness ($\approx 80$ nm), because of which the destructive effects of moisture attack would become more prominent. To further evaluate the operational stability of the ensuing LEDs, time-dependent EL measurement was performed, without using epoxy or silica encapsulation for protection. It is seen that luminance of the resulting LEDs gradually decreased over time, which retained 50% of its initial intensity at $T = 500$ s (Figure S18, Supporting Information). Further study is required to clarify the possible degradation pathways and mechanisms under electric field strengths, with the aim of improving their operational stability.

We have also prepared UV-pumped down-conversion LEDs by directly pressing the MA$_2$CuCl$_3$ powders onto a commercial UV LED chip (310 nm), without using epoxy or silica encapsulation for protection. Figure 5a shows the photograph of the as-fabricated LEDs that emit bright and uniform warm white light, which features CIE color coordinates of (0.44, 0.50) and CCT of
higher operational stability of the UV-pumped MA\(_2\)CuCl\(_3\) LEDs and direct correlation with the stability of the as-bought 310 nm LEDs fall rapidly to 50% at \(\approx 5\) V. Such decline trend is found to have a direct correlation with the stability of the as-bought 310 nm LED chips (Figure S20, Supporting Information). We foresee that a higher operational stability of the UV-pumped MA\(_2\)CuCl\(_3\) LEDs can be achieved by using a more stable UV chip.

3. Conclusions

This work provides a simple, low-cost, and effective method for preparing centimeter-level MA\(_2\)CuCl\(_3\) single crystals and functional thin films, which represent a new kind of efficient warm white luminescent material based on organic–inorganic cuprous chloride. The observations of the broadband emission as well as the high PLQYs (\(\approx 97\%\) without doping) in MA\(_2\)CuCl\(_3\) single crystals were rationalized by means of temperature-dependent PL measurements and DFT calculations, which unveil its exceptionally strong exciton–phonon coupling and unique spatial isolation of photo-excited holes and electrons. Further, we developed a novel methanol-based approach to deposit MA\(_2\)CuCl\(_3\) thin films with uniform morphology and bright PL. Prototype EL devices and down-conversion LEDs are fabricated with MA\(_2\)CuCl\(_3\) thin films and single crystals, respectively, which show desirable warm white-light emission yet still need significant improvement in efficiency to fulfill the requirements for indoor lighting. We foresee that our study will prompt future research on hybrid-type Cu\(^+\)-based compounds and their use in single-component warm-WLEDs.
