Abstract—Acetylcholinesterase activity and pseudocholinesterase activity were examined in plasma and in striated muscles (whole heart and diaphragm muscles) of diabetic KK-CA\textsuperscript{Y} mice. Both activities of acetylcholinesterase in heart muscle and pseudocholinesterase in plasma were significantly increased in diabetic KK-CA\textsuperscript{Y} mice compared to pre-diabetic KK-CA\textsuperscript{Y} mice. Both acetylcholinesterase and pseudocholinesterase activities in skeletal muscle were not changed by the diabetic state. The increases in activity of plasma pseudocholinesterase was significantly correlated to the increase in blood glucose level in alloxan-, streptozotocin (STZ)-diabetic ddY mice and diabetic KK-CA\textsuperscript{Y} mice. The increase was not correlated to the body weight in non-diabetic female-KK-CA\textsuperscript{Y} mice. Furthermore, the activity of heart acetylcholinesterase was significantly correlated with the activity of plasma pseudocholinesterase ($r=0.79$, $P<0.01$). The activities of acetylcholinesterases in heart muscles from STZ- and alloxan-diabetic ddY mice also tended to increase. The hypersensitivity of the pulse rate to a low dose (1 mg/kg) of acetylcholine was correlated to the activity of plasma pseudocholinesterase ($r=-0.51$, $P<0.05$). These results demonstrate that the activities of plasma pseudocholinesterase were increased by the diabetic state being associated with the increasing alteration of cardiac sensitivity to acetylcholine in the whole body.

Cardiac dysfunction and hypertension occur in experimental animals and humans with diabetes mellitus (1, 2). We have previously reported that both the increase in basal pulse rate and basal blood pressure in the diabetic state of streptozotocin-treated mice and diabetic KK-CA\textsuperscript{Y} mice reflects the anticholinergic state (3). The resulting basal anticholinergic state is considered to be balanced both by parasympathetic and sympathetic control. The cardiac hypersensitivity to acetylcholine is induced by the diabetic state (4, 5). The sensitivity to acetylcholine is considered to be closely related to the activity of cholinesterase. Histochemical stains for acetylcholinesterase (AChe) have shown that this enzyme is more rich in the sino-atrial node, Purkinje fibers, and atrio-ventricular node than in either atrial or ventricular myocardium, indicating a strong cholinergic innervation in these areas (6). The activities of pseudochoolinesterase (pseudochE) is reported to be higher than that of AChe in the atria of normal rats (7). In the present study, the activities of AChe and pseudochE in heart muscle and in plasma was examined in diabetic mice, and we further investigated the relationship between the ChE activities and the hypersensitivity to acetylcholine of the pulse rate caused by the diabetic state.
Materials and Methods

Animals: Genetically inbred diabetic KK-CA\(^+\) male mice (A\(^a\)BBCC) (8) (31–36 weeks of age, 28.1–45.5 g body weight, 22.0–31.2 mM blood glucose (BG) level); prediabetic KK-CA\(^+\) male (15–16 weeks of age, 27.0–40.8 g body weight, 6.1–10.3 mM BG level); and female KK-CA\(^-\) mice (12–26 weeks of age, 23.0–60.0 g body weight, 4.4–23.2 mM BG level) of the same strain were used. KK-CA\(^+\) mice were produced in our laboratory by mating male KK-CA\(^+\) mice (A\(^a\)BBCC) with female KK-C mice (aaBBCC).

The ddY strain of mouse with streptozotocin (STZ) and alloxan-induced diabetes was also used. This strain of mouse was purchased from Japan Shizuoka Laboratory Center. STZ (Sigma, 150 mg/kg) or alloxan monohydrate (Nacalai, 85 mg/kg) was dissolved in 0.9% NaCl just before use and injected once into the tail veins of 4-week-old ddY male mice (20.2–24.6 g body weight). Age-matched, non-diabetic ddY mice and ddY mice with chemically induced diabetes were used 4 to 5 weeks after the injection.

Mice were maintained under a constant temperature (23±1 °C), fed the usual laboratory diet (CA-1, Japan Clea) and tap water freely, and with lights on from 8 a.m. to 6 p.m.

The blood samples were obtained at 10 a.m. from the orbital vein plexus. The BG levels in the non-fasted state were measured by a glucose oxidase method using a Beckman glucose analyzer (Fullerton, CA, U.S.A., Type II). The BG levels were confirmed just before isolation of the heart muscles.

Cholinesterase activity: Thirty microliters of blood was obtained from the periorbital venous plexus of mice, diluted four times with 0.9% NaCl containing heparin (20 U/ml), and centrifuged at 3,000 rpm for 10 min at 4°C. The diluted sample of plasma was stored at 4°C and assayed for cholinesterase activity within 24 hr. AChE activity was assayed by a modification of the method of Ellman et al. (9) in a reaction medium containing 0.3 mM 5,5'-dithio-bis(2-nitrobenzoic acid) (DTNB)—0.1 M of phosphate buffer (pH 8.0). An 0.2-ml sample of heart muscle extract or a 10-μl sample of plasma was added to the reaction medium. After incubation at 37°C for 30 min to inactivate pseudoChE completely in the presence of 0.1 mM ethopropazine hydrochloride, the reaction was initiated by adding acetylthiocholine iodide (at the final concentration of 0.5 mM) as a substrate (total volume, 3.12 ml). The reaction mixture was incubated at 37°C for 30 min, and then the reaction was stopped by adding 1 mM of neostigmine methylsulfate per liter. The pseudoChE activity was measured by the same method as above, by adding 0.5 mM butyrylthiocholine iodide instead of acetylthiocholine and 0.01 mM BW284C51 (1,5-bis(4-allyl dimethyl ammoniumphenyl)pentane-3-one dibromide, an AChE inhibitor) instead of ethopropazine. A blank assay was performed by using the same volume of phosphate buffer instead of sample. Both ChE activities were measured by following the increase in absorbance at 415 nm of the yellow compound (5-thio-2-nitrobenzoic acid) in a spectrophotometer (101, Hitachi). Activity is presented in units of micromoles of substrate hydrolyzed per min per gram wet weight of heart muscle or per ml of plasma. The following drugs or reagents were used: acetylthiocholine iodide, S-butyrylthiocholine iodide, 5,5'-dithio-bis(2-nitrobenzoic acid) (DTNB), bacitracin, benzamidine hydrochloride, N-ethylmaleimide (Wako), neostigmine methylsulfate, ethopropazine hydro-
chloride, BW284C51, heparin, pepstatin A (Sigma), urethane and Triton X-100 (Nacalai).

Measurement of pulse rate: The pulse rate were determined by a tail-artery-cuffing technique using a photoelectric sensor plethysmograph in unheated and conscious mice (PS-200, Riken Kaihatsu) (3). The values of pulse rate obtained by this technique have been confirmed by using electrocardiography and a direct cannulation method performed simultaneously under urethane anesthesia.

Statistical analysis: Differences between diabetic and non-diabetic or prediabetic mice were analyzed for significance by using Student's range test. AChE, pseudoChE, and BG level, or pseudoChE, BG level, and body weight were analyzed for multiple correlation (10).

Results

Diabetic state-induced change in plasma pseudocholinesterase and heart or skeletal muscle acetylcholinesterase from prediabetic and diabetic KK-CA\(^+\) mice: Both the activities of AChE and pseudoChE in the diaphragm muscle were not changed by the diabetic state in KK-CA\(^+\) mice (Fig. 1a) and in diaphragm muscles of STZ-diabetic and alloxan-diabetic mice (data not shown). The activity of AChE in skeletal muscle was 2.5-fold greater than that in heart muscle, although the activity of pseudoChE in skeletal muscle was the same as that in heart muscle (Fig. 1b).

In the diabetic KK-CA\(^+\) male mice, the AChE activity in the heart and the pseudoChE activity in the plasma were significantly increased when compared to the prediabetic one (Fig. 1c).

Correlation among heart acetylcholinesterase, plasma pseudocholinesterase, blood glucose level and body weight: Blood glucose levels were 7.6±0.5 (n=8) and 25.8±0.9 mM (n=10) in the prediabetic and diabetic KK-CA\(^+\) mice, respectively.

Fig. 1. Acetylcholinesterase (AChE) activity and pseudocholinesterase (pseudoChE) activity in skeletal muscle (a), heart muscle (b), and in plasma (c) from prediabetic and diabetic KK-CA\(^+\) mice. Each column represents the mean±S.E.M. of 6 to 10 animals. **P<0.01, significantly different from prediabetic KK-CA\(^+\) mice by Student's range test.
CAV male mice and were 7.4±0.3 (n=10), 29.1±1.1 (n=10), and 27.2±1.0 mM (n=10) in the non-diabetic, STZ-diabetic and alloxan-diabetic ddY mice, respectively. In a correlation analysis of two parameters in KK-CA\textsuperscript{V}-, STZ- and alloxan-diabetic male mice, the activity of the heart AChE was correlated positively with the activity of plasma pseudoChE. Activities of plasma pseudoChE were correlated positively with the blood glucose levels (Fig. 2, Table 1). In the obese KK-CA\textsuperscript{V} female mice (50.5±1.1 g body weight, n=61) compared to the diabetic KK-CA\textsuperscript{V} male mice (39.8±0.4 g, n=306), the activity of plasma pseudoChE was not correlated with the body weight. No correlation between AChE activity and age was observed in KK-CA\textsuperscript{V} mice (data not shown).

**Diabetic state-induced changes in heart acetylcholinesterase and plasma pseudocholinesterase activity in ddY mouse with streptozotocin or alloxan:** The activities of AChE and pseudoChE in the heart muscle or in the plasma from STZ- or alloxan-diabetic ddY mice were compared to those from the non-diabetic mice (Fig. 3). The AChE activity in the heart muscle tended to be higher in both diabetic mice than in the non-diabetic ones. The pseudoChE activity in the plasma was significantly (P<0.01) increased in the alloxan-diabetic mice compared to the non-diabetic ones, while it tended to be higher in the STZ-diabetic mice. On the other hand, the pseudoChE activity in the heart muscle and

the AChE activity in the plasma were not changed by the diabetic state.

Multiple correlation among the acetylcholine-induce pulse rate response, the dose of acetylcholine and the activity of plasma pseudocholinesterase in the prediabetic and the diabetic KK-CA\(^+\) mice: The multiple relationships among the ACh-induced pulse rate response, the dose of acetylcholine, and the activity of plasma pseudoChE were three-dimensionally plotted for the KK-CA\(^+\) male mice (Fig. 4). As the dose of acetylcholine was increased from 1 to 30 mg/kg, the pulse rate responses were changed to the negative direction from the positive one. Although the multiple correlation was not observed among the above three parameters, the ACh-induced pulse rate responses were negatively correlated with the activity of plasma pseudoChE only at 1 mg/kg acetylcholine \((r=-0.51, n=16, P<0.05)\).

Discussion

The present study demonstrated that both activities of AChE in the heart muscle and pseudoChE in the plasma were increased in parallel by the diabetic state of KK-CA\(^+\) mice. The pseudoChE in the heart muscle was not changed by the diabetic state. The AChE activity was higher in the heart muscle from the diabetic KK-CA\(^+\) mice than from the pre-
diabetic mice, and it tended to increase in the heart muscle from STZ- and alloxan-diabetic ddY mice. The activities of heart AChE and plasma pseudoChE were significantly correlated, respectively, with the BG level in the KK-CA\(^2\) male mice, indicating the serious involvement of the glucose metabolism in ChE activities. An increase in the ChE activity may decrease the effective concentration of ACh acting on the myocardial receptors. Some investigators reported that the AChE activity in the heart decreased in STZ-diabetic rats, that acetylcholine contents in the nerve ending increased, and that postsynaptic muscarinic receptors were down-regulated (4, 11). This apparent discrepancy may be due to a difference in the region of the heart used for the assay of AChE activity. They used the right atrium, whereas we used the whole heart, because the aim in the present study was restricted to the relation between the activity of cholinesterase in the whole heart and the pulse rate to ACh in the whole body.

The AChE activity increases with age (12). However, no correlation between AChE activity and age was observed in KK-CA\(^2\) male mice (data not shown). The lower extent of increase of AChE activity in the heart muscle of STZ- or alloxan-diabetic mice may be due to the short term duration (4–5 weeks) compared to the long-term duration (15–20 weeks) of diabetes (KK-CA\(^2\) mice). The increase in heart AChE activity seemed not to be related with a hypertrophy of the heart muscle, because the wet weights of heart muscles in diabetic KK-CA\(^2\) mice were not different from those in the prediabetic ones (13). The plasma pseudoChE activity was higher in the diabetic KK-CA\(^2\) mice than in the prediabetic ones. An abnormality in lipid metabolism may cause the induction of pseudoChE in the liver of the diabetic mice as shown in the experimental obese mice (14). Since there were no correlations between plasma pseudoChE activity and body weight in the KK-CA\(^2\) female mice, the increase in plasma pseudoChE can not be attributed to obesity.

The blood insulin levels in diabetic KK-CA\(^2\) male mice are 4.7-fold higher than those in KK-C male mice, but only 1.2-fold lower than that in KK-CA\(^2\) female mice (8). The high level of cholinesterase activity in the diabetic state, therefore, seems not to be related to the insulin level.

The plasma AChE activity was 5- to 10-fold less than the plasma pseudoChE activity, and it was not changed by the diabetic state. Usually, the regulation of AChE is tissue-specific, whereas pseudoChE depends on a homeostatic type of regulation through the whole body (15). The present study indicated that AChE in the heart muscle and pseudoChE in the plasma were regulated in parallel in the diabetic KK-CA\(^2\) mice. Whether the positive correlation between both ChE activities has an important meaning is not clear. Based on the parallel regulation of heart AChE activity and plasma pseudoChE activity, the relationships between plasma pseudoChE activity and alteration of the sensitivity of the pulse rate to acetylcholine were analyzed in diabetic KK-CA\(^2\) mice. A negative correlation was observed only at a low dose of acetylcholine (1 mg/kg), which may produce the critical concentration of acetylcholine in the plasma enabling its hydrolysis, by plasma ChE. The heart rate and the contractile response in skeletal muscles are generally hypersensitive to acetylcholine in the diabetic state (16). These hypersensitivities may be caused in part by the increase in the activity of plasma ChE. The effects on heart rate are balanced both by parasympathetic and sympathetic control in the non-diabetic state, but are unbalanced in the diabetic state. Generally, such an unbalanced state may cause a deflection syndrome (over-parasympathetic) (Reilly phenomena; 17, 18) due to a low level of acetylcholine in the whole body.

In conclusion, AChE activity in the heart muscle and pseudoChE activity in the plasma were increased in parallel in diabetic KK-CA\(^2\) mice. The same tendency was observed in the STZ- and alloxan-diabetic ddY mice. The increase in the ChE activities in the diabetic state may contribute to the increasing alterations of cardiac sensitivity to acetylcholine in the whole body.
