We present extensive numerical simulations of the Axelrod’s model for social influence, aimed at understanding the formation of cultural domains. This is a nonequilibrium model with short range interactions and a remarkably rich dynamical behavior. We study the phase diagram of the model and uncover a nonequilibrium phase transition separating an ordered (culturally polarized) phase from a disordered (culturally fragmented) one. The nature of the phase transition can be continuous or discontinuous depending on the model parameters. At the transition, the size of cultural regions is power-law distributed.

Recently, the study of complex systems entered social science in order to understand how self-organization, cooperative effects and adaptation arise in social systems [1]. In this context the use of simple automata or dynamical models often elucidates the mechanisms at the basis of the observed complex behaviors [1,2].

In this spirit, R. Axelrod has recently proposed an interesting model to mimic how dissemination of culture works [3,4]. Culture is used here to indicate the set of individual attributes, such as language, art or technical standards subject to social influence, i.e. that can be changed as effect of mutual interactions. The automaton does not consider the effect of central institutions or mass media and focuses on the self-organization resulting from a simple local dynamics representing the social influence. This dynamics is assumed to satisfy two simple properties: i) individuals are more likely to interact with others who already share many of their cultural attributes; ii) interaction increases the number of features that individuals share. Starting from an initial state with features distributed randomly this leads to the formation and coarsening of regions of shared culture.

In this Letter we carry out an accurate numerical analysis of Axelrod’s model that unravels a remarkably rich behavior, not detected in previous investigations. Depending on the initial degree of disorder, the model undergoes a phase transition separating an ordered from a disordered phase. The ordered phase is characterized by the growth of a dominant cultural region spanning a large fraction of the whole system. On the contrary, in the disordered phase the system freezes in a highly fragmented state with a nontrivial distribution of the sizes of cultural regions. Such a fragmented configuration is reached in a finite time, which diverges at the phase transition. In the whole ordered phase instead, the coarsening process lasts for a time proportional to the system size, before freezing into the culturally polarized state. Interestingly, the nature of the transition turns from continuous to discontinuous when the number of cultural features is increased. Close to the transition, the distribution of region sizes follows a power law in agreement with the results of Ref. 2 on the statistical analysis of the diversity of languages. Some of these features are captured by a mean field approximation that we discuss below.

Axelrod’s model is defined on a square lattice of linear size $L$. On each site $i$ there is a set of $F$ integer variables $\sigma_{i,f}$ which define the cultural “features” of the individuals living on that site. In the original model, each feature $f = 1, \ldots, F$ on each site $i$ is initially drawn randomly from a uniform distribution on the integers between 1 and $q$. The parameter $q$ is a measure of the initial cultural variability (i.e. disorder) in the system. Here, we relax the constraint of integer $q$ by using a Poisson distribution $\text{Prob}(\sigma_{i,f} = k) = q^k e^{-q}/k!$, that allows $q$ to be a positive real number. Though the results are qualitatively the same, our choice is more convenient to study the behavior of the model as $q$ varies.

At each time step, a pair of nearest neighbor sites $i$ and $j$ is randomly chosen. A feature $f$ is chosen randomly and if $\sigma_{i,f} \neq \sigma_{j,f}$ nothing happens. If instead $\sigma_{i,f} = \sigma_{j,f}$ then an additional feature $f'$ is randomly chosen among those taking different values across the bond, $\sigma_{i,f'} \neq \sigma_{j,f'}$. Such a feature is then set equal: $\sigma_{i,f'} = \sigma_{j,f'}$. A “sweep” of the lattice, i.e. $L^2$ such time steps, defines the time unit as usual. Axelrod’s model (at least in the original formulation) can be seen as $F$ coupled voter models [3].

During the dynamical evolution the total diversity, measured as the number of different values of a feature $f$ which are present in the system, always decreases. Clearly if all features are equal across a bond ($\sigma_{i,f} = \sigma_{j,f}, \forall f$) or if they are all different ($\sigma_{i,f} \neq \sigma_{j,f}, \forall f$) no change can occur on the bond $ij$. A configuration such that, on each bond, either all features are equal or they are all different is an absorbing state. Dynamics will stop if such a state is reached. There are clearly many absorbing states: The dynamics on any finite lattice converges to one of them. The final state can be characterized by the distribution of cultural region sizes, where a region is defined as the connected set of sites sharing exactly the...
The dynamical evolution is characterized by the competition between the disorder of the initial configuration and the ordering drive due to the local social interactions. It is intuitively clear that when $q$ is small the initial state is almost completely uniform, whereas for large values of $q$ almost all sites have features $\sigma_i f$ totally different from those of their nearest neighbors. In the two cases we expect the system to converge to a uniform or a highly fragmented state, in which interaction or disorder dominate, respectively. In order to understand how these two limit situations are connected as $q$ varies, we have simulated the Axelrod’s model for a number of features ranging from $F = 2$ to 10 and sizes up to $L = 150$. We first discuss the dependence of the final state on the parameters $q$ and $F$ and then the dynamical behavior of the model.

### The frozen state

In any finite lattice the dynamics converges to a frozen absorbing state. The existence of a transition in the properties of the final absorbing states is very clear from the plot (Fig. 1) of the average size of the largest region $\langle s_{\text{max}} \rangle$ as a function of $q$ for $F = 10$: For $q = q_c \approx 300$ we observe a sharp transition characterized by a sudden drop of $\langle s_{\text{max}} \rangle / L^2$ which becomes steeper and steeper for increasing sizes $L$. This points to the existence of a transition between a “culturally polarized phase” for $q < q_c$, where one of the regions has a size of the order of the whole system, and a “culturally fragmented” phase, where all domains are finite. The transition is of the first order, with the size of the largest region having a finite discontinuity at $q = q_c$. Note also that, for $q < q_c$, the largest domain approaches a unitary density, i.e. it invades the whole system. This scenario holds for all values $F > 2$ investigated.

The situation is different for $F = 2$ (inset of Fig. 1): The fraction occupied by the largest cluster $\langle s_{\text{max}} \rangle / L^2$ vanishes continuously as $q \rightarrow q_c^-$. The difference between $F = 2$ and $F > 2$ is confirmed and clarified by the study of the size distribution of cultural regions at the transition. Let $P_L(s, q)$ be the probability distribution of regions of $s$ sites in a system of size $L$. The cumulated distribution is plotted in Fig. 2 for several $F$ and values of $q$ around the transition. Fig. 2 shows that $P_L(s, q)$ decays as a power law $s^{-\tau}$ and that the exponent $\tau$ is universal ($\tau \approx 2.6$) for $F > 2$ but takes a different value for $F = 2$ ($\tau \approx 1.6$). In particular we find $\tau_{F>2} > 2$ and $\tau_{F=2} < 2$.

The different nature of the transition for $F$ equal or greater than 2 can be related to the exponent $\tau$. Let $N(q, L)$ be the total number of regions in the system. Requiring the total area to be $L^2$ leads to

$$L^2 = N(q, L) s = N(q, L) \sum_{s=1}^{\infty} s P_L(s, q). \quad (1)$$

For $q > q_c$, there are $N(q, L) \sim L^2$ domains of finite size and the sum on $s$ is finite as $L \rightarrow \infty$. On the other hand, for $q < q_c$, there are few small domains and a large one of size $s_{\text{max}} \sim L^2$. Hence the probability distribution can be written in the generic scaling form $P_L(s, q) = s^{-\tau} F(s/s_{\text{co}}) + A(q) \delta_{s_{\text{max}}} \sim L^2$. The nature of the transition is identified by the behavior of $A(q)$ for $q \rightarrow q_c^-$. For $\tau > 2$, similarly to what happens in percolation theory, the transition occurs through the divergence of $s_{\text{co}}$ and hence of a correlation length, as $q \rightarrow q_c^-$. This causes the divergence of $\langle s \rangle$ in Eq. (1) (because $s P_L(s, q) \sim s^{1-\tau}$ with $\tau < 2$), which matches the divergence of the l.h.s. of Eq. (1) as $L \rightarrow \infty$, through usual finite size scaling arguments. Indeed, at $q = q_c$, the cut-off diverges with the system size as $s_{\text{co}} \sim L^{\beta}$. On the other side of the transition a similar divergence of the cutoff $s_{\text{co}}$ occurs and the amplitude $A$ must vanish as $q \rightarrow q_c^+$. This scenario is typical of second order phase transitions and agrees with the value $\tau < 2$ found for $F = 2$ and Fig. 1.

When $\tau > 2$ the previous scenario cannot hold: For $q > q_c$, even if $s_{\text{co}}$ diverges, the sum on $s$ in Eq. (1) remains finite. Hence as $q \rightarrow q_c^+$ the number of domains $N(q, L)$ must remain of order $L^2$. On the other side of the transition, the $L^2$ term in the l.h.s. of Eq. (1) can only be matched by the term $s_{\text{max}} \sim L^2$. Since no divergence arises from the sum on small components as $q \rightarrow q_c^-$, the amplitude $A$ of the large component must remain of order one in this limit. We then conclude that, as $q$ crosses $q_c$, the nature of the distribution changes abruptly for $\tau > 2$. In particular the amplitude $A(q)$ exhibits a discontinuous jump across the transition $\tau = 2$.

### Dynamics

In order to investigate the model dynamics we study the density $n_a$ of active bonds. An active bond is a bond across which at least one feature is different and at least one is equal, so that there can be some dynamics. This quantity is indicative of the dynamical state of the system, being zero in frozen configurations. In Fig. 3 we show the behavior of $n_a$ as a function of time for different values of $q$ and $F = 10$. For large values of $q$, after a short initial transient, the density of active bonds decays rapidly and the system locks into a frozen configuration in a finite time. For small $q$ instead, $n_a(t)$ displays a slow decay with a large majority of bonds in the active state until it falls abruptly for long times. As the system size is increased, the slow decay extends to longer and longer times: The cut-off time, at which activity suddenly dies scales as $t_{\text{co}} \sim L^2$ as shown in the inset of Fig. 3. For a large range of intermediate $q$ values, $n_a$ first decreases almost to zero but then rises again towards a peak of activity, from which the slow decay begins.

The dynamics is essentially a coarsening process of homogeneous regions. When the process lasts only for a finite time, as for $q > q_c$, it gives rise to regions of finite size. On the contrary, for $q < q_c$ the coarsening process goes on for a time $t_{\text{co}} \sim L^2$ and produces a region of size comparable with the whole system. The exponent
z = 2 relating $t_{co}$ to $L$ is the same found in nonconserved phase-ordering \[1\] and in particular in the two-dimensional voter model \[1\], which also exhibits a slow decay of the density of active bonds \[1\].

For an infinite system ($L \to \infty$) and $q < q_c$ the system is indefinitely in a coarsening state. Therefore we can also define the transition as separating two different dynamical regimes, with a fast decay of $n_a$ lasting for a finite characteristic time for $q > q_c$ and a slow, infinitely long decay for $q < q_c$. For $F = 2$ the behavior is qualitatively the same: Noticeably, no evident signature of the different nature of the transition (continuous vs. discontinuous) can be inferred from the dynamical evolution.

The dynamical behavior of the model can be studied within a single bond mean field treatment. Let $P_m(t)$ be the probability that a randomly picked bond is of type $m$ at time $t$, i.e. $m$ features across the bond are equal and $F - m$ are different. At $t = 0$, since features are assigned uncorrelated random values, we have $P_m(0) = \binom{F}{m} \rho_0^m (1 - \rho_0)^{F-m}$ where $\rho_0 = \text{Prob} [\sigma_i, f = \sigma_j, f]$ is the probability that two sites have feature $f$ with the same value at $t = 0$.

In the mean field approximation, $P_m$ satisfies the master equation

$$\frac{dP_m}{dt} = \sum_{k=1}^{F-1} \frac{k}{F} P_k \left[ \delta_{m,k+1} - \delta_{m,k} \right] (g - 1) \sum_{n=0}^{F} \left( P_n W_{n,m}^{(k)} - P_m W_{m,n}^{(k)} \right), \quad (2)$$

where $g$ is the lattice coordination number and $W_{n,m}^{(k)}$ is the transition probability of a $n$-type bond to a $m$-type bond due to the updating of a $k$-type neighbor bond. This equation describes how the number of bonds of type $m$ is affected by the dynamics: $P_k k/F$ is the probability to select a bond of type $k$ and one of the $k$ features which are equal across it. If $k = m-1$ a new bond of type $m$ is created whereas if $k = m$ one bond of type $m$ is deleted. This explains the first two terms on the r.h.s. of Eq. (2). But the change of a feature of the site may also affect the state of the other $g - 1$ bonds connecting such site to its neighbors. The remaining terms in Eq. (4) take into account this possibility. We can compute the probabilities $W_{n,m}^{(k)}$ by analyzing in detail each possible process. Let us consider e.g. a type $k = 1$ bond adjacent to a type $n = 0$ one. Without loss of generality we can let the features on the extreme sites of the $1$ bond be $(0, 0, \ldots, 0)$ and $(0, \sigma_2, \ldots, \sigma_F)$, with $\sigma_j \neq 0$. The latter site is shared also by the $0$ bond whose other site has features $(\sigma_1', \sigma_2', \ldots, \sigma_F')$ with $\sigma'_1 \neq 0$ and $\sigma'_j \neq \sigma_j$ for $j > 1$. When the $1$ bond becomes a type $2$ bond, $\sigma_2 \to 0$ the neighbor $0$ bond can either remain a $0$ bond, if $\sigma'_2 \neq 0$ or it can become a $1$ bond if $\sigma'_2 = 0$. In the spirit of the mean field approximation we introduce the probability $\rho = \text{Prob} (\sigma'_2 = 0)$ which now becomes time dependent, as we shall see. Then $W_{0,0}^{(1)} = 1 - \rho$ and $W_{0,1}^{(1)} = \rho$. In much the same way we can compute the other transition rates. For example, if $F = 2$, the only non zero elements are

$$W_{0,0}^{(1)} = 1 - \rho, \quad W_{0,1}^{(1)} = \rho,$$

$$W_{1,0}^{(1)} = 1/2, \quad W_{1,1}^{(1)} = (1 - \rho)/2, \quad W_{1,2}^{(1)} = \rho/2 \quad (3)$$

$$W_{2,1}^{(1)} = 1.$$
