IMPROVING END-TO-END SPEECH RECOGNITION WITH
PRONUNCIATION-ASSISTED SUB-WORD MODELING

ABSTRACT
In recent years, end-to-end models have become popular for application in automatic speech recognition. Compared to hybrid approaches, which perform the phone-sequence to word conversion based on a lexicon, an end-to-end system models text directly, usually as a sequence of characters or sub-word features. We propose a sub-word modeling method that leverages the pronunciation information of a word. Experiments show that the proposed method can greatly improve upon the character-based baseline, and also outperform commonly used byte-pair encoding methods.

Index Terms—end-to-end models, speech recognition, sub-word modeling

1. INTRODUCTION
In recent years, end-to-end models have become popular among the speech community. Compared to hybrid-systems that consist of separate pronunciation, acoustic and language models, all of which need to be independently trained, an end-to-end system is a single neural-network which implicitly models all three. Although modular training of those components is possible [1], an end-to-end model is usually jointly optimized during training. Among the different network typologies for end-to-end systems, the attention-based encoder-decoder mechanism has proven to be very successful in a number of tasks, including automatic speech recognition (ASR) [2] [3] [4] and neural machine translation.

Due to lack of a pronunciation dictionary, most end-to-end systems do not model words directly, but instead model the output text sequence in finer units, usually characters. This is one of the most attractive benefits of an end-to-end system, which greatly reduce the complexities of the system. This approach, however, works best for languages where there is a strong link between the spelling and the pronunciation, e.g. Spanish. For languages like English, however, this approach might limit the performance of the system, especially when there is no enough data for the system to learn all the subtleties in the language. On the other hand, linguists have developed very sophisticated pronunciation dictionaries of high quality for most languages, which can potentially improve the performance of end-to-end systems [5].

Sub-word representations have recently seen their success in ASR [6]. Using sub-word features has a number of benefits for ASR, in that it can speed up both training and inference, while helping the system better learn the pronunciation patterns of a language. For example, if a sub-word algorithm segments the word “thank” into “th-an-k”, this will make it easier for the ASR system to learn the association between the spelling “th” and the corresponding sound, which is not a concatenation of “t” and “h”. However, it should also be noted that lots of these methods are designed for text processing tasks such as neural machine translation, and thus are only based on word spellings and do not have access to pronunciation information. Hence, it is possible for these algorithms to break a word sequence into units that do not imply well-formed correspondence to phonetic units, making it even more difficult to learn the mapping between phonemes and spellings. For example, if a sub-word model sees a lot of “hys” in the data, it might process the word “physics” into “p-hys-ics”, making the association with the “f” phoneme hard to learn. We argue it is far from ideal to directly apply these methods to ASR and improvements should be made to incorporate pronunciation information when determining sub-word segmentations.

This paper is an effort on this direction by utilizing a pronunciation dictionary and an aligner. We call this method pronunciation-assisted sub-word modeling (PASM), which adopts fast_align [7] to align a pronunciation lexicon file and use the result to figure out common correspondence between sub-word units and phonetic units. We then use the statistics collected from this correspondence to guide our segmentation process such that it better caters the need of ASR. The proposed method would work on a variety of languages with known lexicon, and would also work in other tasks, e.g. speech translation.
This paper is organized as follows, in section 2 we describe prior work; in section 3 we give a detail description of our proposed method, followed by section 4 where we report our experiment results. We will conduct an analysis and discussion of the results in section 5 and then talk about future work in section 6.

2. RELATED WORK

The use of using a pronunciation dictionary is the standard approach in hybrid speech recognition. [8] use the phone-level alignment to generate a probabilistic lexicon and proposed a word-dependent silence model to improve ASR accuracy; for use in end-to-end ASR models, [5] investigated the value of a lexicon in end-to-end ASR. Sub-word methods have a long history of application in a number of language related tasks. [9] used minimal description length as the criteria for sub-word modeling for speech recognition. [10] used sub-words units in particular for detecting unseen words. [11] used sub-words units in building text-independent speech recognition systems. [12] improved upon sub-word methods in WFST-based speech recognition.

Apart from the application in ASR, the most recent tide of adopting sub-word representations is largely driven by neural machine translation. [13] propose to use byte pair encoding (BPE) [14] to build a sub-word dictionary by greedily keep the most frequent co-occurring character sequences. Concurrently, [15] borrow the practice in voice search [16] to segment words into wordpiece which maximizes the language model probability. [17] augments the training data with sub-word segmentation sampled from the segmentation lattice, thus increasing the robustness of the system to segmentation ambiguities.

3. METHOD

3.1. Method Overview

The high-level idea of our method is as follows: instead of generating a sub-word segmentation scheme by collecting spelling statistics from the tokenized text corpus, we collect such statistics only from the consistent letter-phoneme sequence pairs extracted from a pronunciation lexicon. The automatically extracted consistent letter-phoneme sequence pairs can be treated as an induced explanation for the pronunciation of each word, and hence, such pairs will ideally contain no letter sequences, i.e. sub-words, that will lead to ill configurations such as "p-hys-ics".

We generate sub-word segmentation schemes in 3 steps:

1. Using an aligner to generate a letter-phoneme alignment for a pronunciation dictionary
2. Extract consistent letter-phoneme sequence pairs from alignment
3. Collect letter-sequence statistics from the consistent letter-phoneme pairs

To simplify the model and generalize to unseen words, we do not perform word-dependent sub-word modeling in this work. Our model generates a list of sub-words, with priorities, and we split any word with those sub-words.

3.2. Method Description

3.2.1. Letter-phoneme Alignment Generation

We use fast_align to generate an alignment between letters and phonemes i.e. its pronunciation, which will be able to find common patterns of letter-sequences that correspond to certain phonetic units. For example, for the alignment shown in Figure 1 it is represented as a set,

\{(0, 0), (1, 1), (2, 2), (3, 2), (4, 3)\}

where each element in the set is a pair of (letter-index, phone-index), both starting from 0. In this case, letters 2 and 3 are aligned to the same phoneme 2. In practice, we could have one-to-one (e.g. “cat”), one-to-many (e.g. “ex”), many-to-one (e.g “ah”) and even many-to-many alignments (linguistically this should not happen for most languages but this is a good indicator of an “outlier” case, e.g. a French word in English that the aligner does not know how to process).

3.2.2. Finding Consistent Letter-phoneme Pairs

Formally, a consistent letter-phoneme pair \((L, P)\) is consisted of a letter-sequence (or sub-word) \(L = (l_1, ..., l_n)\) and a phoneme sequence \(P = (p_1, ..., p_m)\). These pairs are heuristically extracted from the letter-phoneme alignment generated by fast_align, and are then further refined to reduce noise mostly introduced by erroneous alignments.

**Extraction** As fast_align is a re-parametrization of IBM model 2, a typical alignment method for statistical machine translation, it does not limit itself in generating monotonic alignments. There could be cross-overs in its output, like in Figure 2 as well as “null-alignments”, where a letter is aligned to a “null” symbol.

In the case of non-crossing alignments like the one shown in Figure 1 we simply extract each connected sub-sequences.
**Refinement**

Refinement over the consistent letter-phoneme pairs is performed under the following criteria:

1. min-count constraint: \( L \) must occur at least \( N \) times in the training corpus,
2. proportion constraint: of all the words containing \( L \) in the corpus, in at least \( p\% \) of all occurrences it is mapped to a particular phone-sequence \( P \).

In practice we fix \( N = 100 \) and \( p = 50 \). After processing we only keep the selected letter-sequences and their counts in data for future steps, and discard the pronunciations.

### 3.2.3. Collecting Letter Sequence Statistics

Recall that while we use pronunciation lexicon to extract consistent letter-phoneme pairs, our ultimate goal is to collect reliable statistics of the letter sequences (i.e. sub-word) to guide the sub-word segmentation process. Such statistics has nothing to do with phonemes, which means it needs to be marginalized. We perform the marginalization by summing up the counts of each type of letter sequence over all possible types of phoneme sequences.

### 3.3. Text Processing

As with all the sub-word modeling methods, our text processing step takes tokenized word sequences as input and segment them into sequences of sub-word. The segmentation process is essentially a search problem operating on the lattice of all possible sub-word segmentation schemes over the word-level input. This segmentation space is constrained by the complete set of sub-words in the segmentation scheme generated above, with hypothesis priorities assigned by the associated statistics. For example, if both “abc” and “bc” and chosen, and “ab” occurs more often than “bc” according to the statistics, then “abc” would become “ab c” instead of “a bc”.

### 4. EXPERIMENTS

We conduct our experiment using the open-source end-to-end speech recognition toolkit ESPnet [18]. We report the ASR performance on the Wall Street Journal (WSJ) and LibriSpeech (100h) datasets. Our baseline is the standard character-based recipe, using bi-directional LSTMs with projection layers as the encoder, location-based attention, and LSTM decoder, with a CTC-weight of 0.5 during training [4]. To fully see the effect of sub-word methods, we do not perform language model rescoring but report the 1st pass numbers directly.

| Table 1. WER Results of BPE Systems on WSJ |
| Num-BPEs | 50 | 108 | 200 | 400 |
|----------|----|-----|-----|-----|
| dev93    | 20.7 | 19.5 | 21.3 | 24.6 |
| eval92   | 15.2 | 15.6 | 17.7 | 20.0 |

| Table 2. WER Results on WSJ |
|-----------------------------|
| Baseline | PASM | BPE |
|----------|------|-----|
| dev93    | 20.7 | 18.5 | 19.5 |
| eval92   | 15.2 | 14.3 | 15.6 |

| Table 3. WER Results on LibriSpeech |
|------------------------------------|
| dev-clean | dev-other | test-clean | test-other |
|----------|-----------|-------------|-------------|
| Baseline | BPE | PASM | BPE | PASM |
|----------|-----|-----|-----|-----|
| dev-clean | 23.8 | 29.5 | 21.4 |
| dev-other | 52.8 | 53.1 | 50.7 |
| test-clean | 23.2 | 29.5 | 21.3 |
| test-other | 54.8 | 55.3 | 52.8 |

The baseline and proposed PASM system use an explicit “space” character in modeling word boundaries; we also compare our systems with BPE baselines. The BPE procedure follows the algorithm described in [13], and no “space” character is needed because it is taken care of in the encoding. All the PASM segmentation schemes are trained using the lexicon included in its default recipe, and we use \( N = 100 \) and \( p = 50 \). All the other hyper-parameters are independently tuned.

For the WSJ setup, we have kept the number of sub-word units to be the same in BPE and PASM systems (both = 108). The results are shown in Table 2 where we report the word-error-rates on the dev93 and eval92 sets. We see that, the use of BPE improves dev93 performance but hurts performance.
Table 4. Samples of Segmented Text Under the PASM Scheme and BPE Schemes with Various Vocabulary Sizes

| Scheme | Text |
|--------|------|
| original | the sale of the hotels is part of holiday’s strategy to sell off assets and concentrate on property management |
| PASM | the sale of the hotels is part of holiday’s strategy to sell off assets and concentrate on property management |
| BPE-108 | the sale of the hotels is part of holiday’s strategy to sell off assets and concentrate on property management |
| BPE-200 | the sale of the hotels is part of holiday’s strategy to sell off assets and concentrate on property management |
| BPE-400 | the sale of the hotels is part of holiday’s strategy to sell off assets and concentrate on property management |

on eval92. PASM method gives consistent improvements in the 2 datasets.

We also report the more BPE results on WSJ, adjusting number of BPE units in Table 1. We can see that having more BPEs actually hurts the performance. This is likely because of the limited data-size of WSJ, which makes it hard to learn reliable BPE units.

In Table 3, we report the WER results on the LibriSpeech dataset, using the parameters described in [6]. We have seen that PASM significantly improves the character-based baseline; BPEs do not help in this case, possibly due to poor hyper-parameter tuning.

5. ANALYSIS

We here list the output after the BPE procedure of the first sentence in the WSJ training data, and compare that with the result of the PASM algorithm.

From the examples above, we have the following observations,

- The PASM method correctly learns linguistic units, including “le”, “th”, “ay”, “ll”, “ll”, “ss”, “ge”, which correspond to only one phoneme, but were not correctly handled in the BPE case.
- The BPE learns some non-linguistic but frequent-seen units in data, e.g. “the”, “ate”. In particular, the pronunciation associated with “ate” in the 2 occurrences are very different, which might make it harder for the system to learn the associations.

- As the number of BPE units increases, we see more sub-word units that do not conform to linguistic constraints, e.g. “as-s-e-t-s” and “of-f” in BPE-400. In this case, the 2nd “s” “asset” and 2nd “f” in “off” would have to be silent in terms of pronunciation, which would likely confuse the training of end-to-end systems unless there is a huge amount of data.

6. CONCLUSION AND FUTURE WORK

In this work, we propose a sub-word modeling method for end-to-end ASR based on information from their pronunciations. Experiments show that the proposed method gives substantial gains over the letter-based baseline, as measured by word-error-rates. The method also outperforms byte-pair encoding based systems. We postulate that the improvement comes from the fact that, the proposed method learns more natural sub-words for speech tasks, unlike BPE which only take the spelling into consideration.

There are a lot of future work directions that we plan to take. We will design new algorithms for aligning pronunciation dictionaries that is taylored for speech tasks; we will study ways to combine the proposed method with BPE to further improve ASR performances and speed up systems; we also plan to investigate the application of the proposed method in hybrid ASR, machine translation, as well as speech translation.
