Abstract
Maximal neuromuscular power is an important determinant of athletic performance and also quality of life, independence, and perhaps even mortality in patient populations. We have shown that dietary nitrate (NO3−), a source of nitric oxide (NO), improves muscle power in some, but not all, subjects. The present investigation was designed to identify factors contributing to this interindividual variability. Healthy men (n = 13) and women (n = 7) 22–79 year of age and weighing 52.1–114.9 kg were studied using a randomized, double-blind, placebo-controlled, crossover design. Subjects were tested 2 h after ingesting beetroot juice (BRJ) either containing or devoid of 12.3/0.8 mmol of NO3−. Plasma NO3− and nitrite (NO2−) were measured as indicators of NO bioavailability and maximal knee extensor speed (Vmax), power (Pmax), and fatigability were determined via isokinetic dynamometry. On average, dietary NO3− increased (P < 0.05) Pmax by 4.4±8.1%. Individual changes, however, ranged from −9.6 to +26.8%. This interindividual variability was not significantly correlated with age, body mass (inverse of NO3− dose per kg), body mass index (surrogate for body composition) or placebo trial Vmax or fatigue index (in vivo indicators of muscle fiber type distribution). In contrast, the relative increase in Pmax was significantly correlated (r = 0.60; P < 0.01) with the relative increase in plasma NO2− concentration. In multivariable analysis female sex also tended (P = 0.08) to be associated with a greater increase in Pmax. We conclude that the magnitude of the dietary NO3−-induced increase in muscle power is dependent upon the magnitude of the resulting increase in plasma NO2− and possibly female sex.

Introduction
Maximal neuromuscular power is an important determinant of athletic performance and is also highly significant from a clinical perspective, as reductions in power contribute to impaired quality of life, disability, and possibly even mortality in various patient populations (e.g., the elderly (Guralnik et al. 1994), heart failure (HF) patients (Hülsmann et al. 2004)). It is therefore noteworthy that recent studies have demonstrated that acute or chronic supplementation with dietary nitrate (NO3−), a source of nitric oxide (NO) via the enterosalivary pathway.
High versus Low Responders To Dietary Nitrate

A. R. Coggan et al.

(Lundberg and Weitzberg 2009), can influence muscle contractile properties (Haider and Folland 2014; Coggan et al. 2015a,b; Justice et al. 2015; Rimer et al. 2016; Whitfield et al. 2017). In a previous study, for example, we found that acute ingestion of NO$_3^-$ increased maximal knee extensor speed and power in healthy, untrained individuals by 11 and 6%, respectively, (Coggan et al. 2015b). We observed a similar dietary NO$_3^-$-induced enhancement of maximal neuromuscular power in athletes (Rimer et al. 2016), and an even greater increase (i.e., 13%) in patients with HF (Coggan et al. 2015a). NO$_3^-$ (or nitrite (NO$_2^-$)) -induced improvements in muscle contractility have also been observed in some (Haider and Folland 2014; Justice et al. 2015; Whitfield et al. 2017), albeit not all (Hoon et al. 2015), recent studies of voluntary or electrically stimulated isometric exercise.

Based on these previous studies (Haider and Folland 2014; Coggan et al. 2015a,b; Justice et al. 2015; Rimer et al. 2016; Whitfield et al. 2017), it therefore appears that dietary NO$_3^-$ can enhance the inherent contractile properties of human muscle. However, as with NO$_3^-$-induced improvements in endurance performance (Christensen et al. 2013; Boorsma et al. 2014) (or reductions in blood pressure (Kapil et al. 2010)), not all individuals seem to respond equally. Specifically, only about three-fourths of the subjects we have studied previously have demonstrated improvements in muscle speed and/or power with NO$_3^-$ intake. The reason for this variability between individuals is not clear, but it may be related to the extent to which NO$_3^-$ intake increases NO bioavailability. This hypothesis is suggested by the key role played by oral bacteria in reducing ingested NO$_3^-$ to NO$_2^-$, the immediate precursor for NO synthesis via the enterosalivary pathway (Lundberg and Weitzberg 2009). Alternatively and/or in addition, based in part on animal studies it has been proposed that the effects of dietary NO$_3^-$ supplementation are greatest in type II, or fast-twitch, muscle fibers (Jones et al. 2016). The interindividual variability in muscle power improvements that we have observed therefore may be related to differences in muscle type distribution.

The purpose of this study was to test the hypothesis that interindividual differences in the effects of dietary NO$_3^-$ on muscle function are related to interindividual differences in NO production and/or in the percentage of fast-twitch muscle fibers. To do so, we determined the relationship between changes in muscle power due to NO$_3^-$ ingestion and markers of NO bioavailability (i.e., plasma NO$_3^-$ and NO$_2^-$ levels) and muscle fiber type (i.e., maximal knee extensor velocity (Vmax) and fatigability in the absence of NO$_3^-$ intake) in a heterogeneous group of healthy men and women. We recruited subjects widely varying in other characteristics (e.g., age) as well, to determine whether there was any relationship between such factors and the response to dietary NO$_3^-$. The results of this study provide insight into the mechanisms responsible for interindividual differences in the effects of NO$_2^-$ supplementation on muscle power, which may prove useful in optimizing this intervention in both athletes and clinical populations.

**Methods**

**Subjects**

We studied 13 men and 7 women ranging in age from 22 to 79 (mean 47 ± 20) years, in body mass from 52.1 to 114.9 (mean 78.2 ± 16.3) kg, and in body mass index (BMI) from 19.1 to 32.6 (mean 25.8 ± 4.2) kg/m$^2$. All of the subjects were healthy, based upon medical history, physical examination, and standard blood chemistries. Although all were normally active, only two exercised regularly, and none were engaged in training for competitive sports. None of the subjects smoked. Additional exclusion criteria included use of drugs that can block reduction of NO$_3^-$ and NO$_2^-$ to NO (i.e., prescription sex hormones, antacids, proton pump inhibitors, or xanthine oxidase inhibitors) (Lundberg et al. 1994; Obach et al. 2004) or can potentiate the effects of the latter (i.e., phosphodiesterase inhibitors) (Webb et al. 1999). Women who were pregnant or lactating were also excluded. Approval for the study was obtained from the Human Subjects Office at Indiana University and the Human Research Protection Office at Washington University School of Medicine, and all subjects provided written, informed consent. Partial data from some of these subjects has been presented previously (Coggan et al. 2015b).

**Experimental design and protocol**

Each subject was studied twice using a double-blind, placebo-controlled, randomized design. During one trial, subjects were tested after ingesting 140 mL of a commercial beetroot juice (BRJ) supplement (Beet It$^\text{®}$, James White Drinks, Ipswich, UK) containing 12.3 ± 0.8 mmol of NO$_3^-$. During the other trial, they ingested an equal volume of concentrated BRJ from which the NO$_3^-$ had been removed by the manufacturer. A washout period of 1–2 weeks separated the two trials (i.e., NO$_3^-$ vs. placebo). Since use of an antibacterial mouthwash, tooth brushing, or chewing gum can block the conversion of NO$_3^-$ to NO$_2^-$ by oral bacteria (Lundberg et al. 1994; Govoni et al. 2008), subjects were instructed to avoid these behaviors on study days. They were also instructed to avoid high NO$_3^-$ foods throughout the study, with adherence to this instruction verified by analysis of food records by a dietician.

Subjects arrived at the Clinical Research Unit in the morning after avoiding food, caffeine, or alcohol intake. The subjects were instructed to avoid high NO$_3^-$ foods throughout the study, with adherence to this instruction verified by analysis of food records by a dietician.
determine the subject’s velocity data were then fit with a parabolic function to observed at each velocity by that velocity. The power-power was calculated by multiplying the peak torque and smoothed to eliminate artifacts, after which peak between each set. The resulting torque data were filtered 1.57, 3.14, 4.71, and 6.28 rad/sec, with 2 min of rest (Coggan et al. 2015a,b). Briefly, each subject performed the contractile properties of the knee extensor muscles of the subject’s dominant leg were determined using an isokinetic dynamometer (Biodex System 4 Pro, Biodex Medical Systems, Shirley, NY) as previously described (Coggan et al. 2015a,b). Briefly, each subject performed 3–4 maximal knee extensions at angular velocities of 0, 1.57, 3.14, 4.71, and 6.28 rad/sec, with 2 min of rest between each set. The resulting torque data were filtered and smoothed to eliminate artifacts, after which peak power was calculated by multiplying the peak torque observed at each velocity by that velocity. The power-velocity data were then fit with a parabolic function to determine the subject’s $V_{\text{max}}$ and maximal power ($P_{\text{max}}$). After an additional 2 min of rest, the subject performed 50 consecutive maximal knee extensions at angular velocity of 3.14 rad/sec to determine their resistance to fatigue (i.e., fatigue index, $\%$ decrease in power from first 1/3 to last 1/3 of the test) during repeated muscle contractions. Following a 10 min rest period, the final plasma samples were obtained after which the subject was fed a light meal and released.

**Data analysis**

Statistical analyses were performed using GraphPad Prism version 7.02 (GraphPad Software, La Jolla, CA). Normality of data distribution was first tested using the D’-tino-Pearson omnibus test. Data from the placebo and NO3− trials were subsequently compared using two-way (treatment x order) ANOVA, with subject as a repeated measures factor within treatment. Intraclass correlation coefficients were calculated from the ANOVA results to quantify the reliability of the data. Standard Pearson product correlations were calculated to explore the relationship between relative changes in $P_{\text{max}}$ as the dependent variable and sex, age, body mass (inverse to NO3− dose in $\mu$mol/kg), BMI, placebo trial $V_{\text{max}}$, placebo trial fatigue index (in vivo indicators of muscle fiber type distribution), percent change in plasma NO3−, or percent change in plasma NO2− as independent variables. The overall false discovery rate was limited to 10% using the Benjamini–Hochberg procedure. As this was an exploratory study, stepwise forward regression was also employed using the same dependent and independent variables, with the $P$ value to enter the model similarly set to 0.10.

**Results**

The effects of ingesting BRJ without or with NO3− on plasma NO3− and NO2− concentrations are shown in Table 1. No significant changes occurred in the placebo trial, whereas during the NO3− trial, both NO3− and NO2− increased significantly. This was accompanied by a significant ($P < 0.05$) elevation in $V_{\text{max}}$, which increased from 12.3 ± 2.5 (range: 9.3–20.2) rad/sec in the placebo trial to 13.2 ± 3.1 (range: 8.4–20.2) rad/sec in the NO3− trial. $P_{\text{max}}$ also increased significantly ($P < 0.05$), that is, from 6.3 ± 2.3 (range: 2.8–10.7) to 6.6 ± 2.4 (range: 2.7–11.8) W/kg. Individual changes varied from −9.6 to +26. % (Fig. 1). On the other hand, the fatigue index was unaltered by NO3− intake, averaging 61 ± 13 (range: 34–78) and 61.6 ± 13.5 (range: 32–78)% during the placebo and NO3− trials, respectively. All three performance measures were highly reliable, with intraclass correlation coefficients of 0.94, 0.98, and 0.89 for $V_{\text{max}}$, $P_{\text{max}}$, and fatigue index, respectively. No adverse effects were observed. These observations confirm and extend our previous findings (Coggan et al. 2015a,b; Rimer et al. 2016). The remainder of our effort therefore focused upon attempting to elucidate the factors responsible for the marked variability between subjects in the response to NO3− intake.

In univariable analyses, the relative increase (i.e., $\Delta$%) in $P_{\text{max}}$ due to dietary NO3− ingestion was not

not correlated with the relative change in plasma NO₃⁻ (Table 3). Female sex also tended to be a positive predictor of relative increases in Pmax in the multivariable analysis (Table 3). In keeping with this, female subjects tended (i.e., $P = 0.06$ by Fisher’s exact test) to be more likely to exhibit a greater-than-average increase in Pmax, that is, to be “high responders” (Fig. 2). Taken together, the relative change in plasma NO₂⁻ concentration and subject sex explained ~40% of the interindividual variation in the effect of NO₃⁻ intake on muscle power (i.e., $R^2$ of multivariable regression = 0.38).

**Discussion**

The purpose of this study was to identify (if possible) factors contributing to interindividual variability in improvements in muscle contractile function resulting from dietary NO₃⁻ intake. Based on previous research, we hypothesized that such differences would be related to differences between individuals in markers of NO bioavailability and/or muscle fiber type. Consistent with the first hypothesis, we found a significant correlation between the relative increase in $P_{\text{max}}$ and the relative increase in plasma NO₂⁻ concentration due to NO₃⁻ ingestion. Our second hypothesis, however, was not supported, as there was no association between the increase in $P_{\text{max}}$ and baseline $V_{\text{max}}$ or fatigue index, in vivo indicators of muscle fiber type distribution (see below). Finally, our data provide preliminary support for the novel hypothesis that, at least in terms of improvements in maximal neuromuscular power, women are more likely than men to benefit from dietary NO₃⁻ supplementation.

Reduction in NO₃⁻ to NO₂⁻ by oral bacteria plays a critical role in the production of NO via the enterosorptive pathway (Lundberg et al. 1994; Govoni et al. 2008; Lundberg and Weitzberg 2009). In fact, this step appears to be possibly rate-limiting, as demonstrated by the much smaller increase in plasma NO₂⁻ versus NO₃⁻ following NO₃⁻ ingestion (Table 1). Accordingly, previous studies have observed a significant correlation between the magnitude of the increase in plasma NO₂⁻ following NO₃⁻ ingestion and the improvement in endurance performance ability (Wilkerson et al. 2012; Hoon et al. 2014). Our results are similar, as we found that interindividual differences in how much plasma NO₂⁻ concentration was elevated by NO₃⁻ intake accounted for about one-third of the variation between individuals in the increase in Pmax. It is possible that this significant correlation reflects a direct effect of NO₂⁻ on muscle contractility. Indeed, in cardiac muscle NO₂⁻ has been shown to nitrosylate cysteine residues of various membrane proteins independently of NO (Montesanti et al. 2014). In skeletal muscle, however, S-nitrosylation is thought to inhibit contractile function; stimulatory effects are held to be the result of NO-dependent soluble guanyl cyclase (sGC)/

**Figure 2.** Relationship of relative changes in maximal knee extensor power ($P_{\text{max}}$) to relative changes in plasma NO₂⁻ concentration in response to dietary NO₃⁻ intake. Open symbols, male subjects. Closed symbols, female subjects. Plasma samples from one female subject were not available for analysis; data for the remaining 19 subjects are therefore shown.
cyclic GMP (cGMP)/protein kinase G (PKG) signaling (Maréchal and Gaily 1999). A direct effect of NO\textsubscript{2} would therefore seemingly not explain the positive correlation we observed between changes in plasma NO\textsubscript{2}\textsuperscript{−} and changes in Pmax. Rather, this observation is consistent with our first hypothesis that interindividual differences in the availability of NO itself contribute to interindividual differences in the extent to which dietary NO\textsubscript{3}\textsuperscript{−} intake increases muscle power.

Although we were able to at least partially confirm our first hypothesis, our data do not support our second hypothesis, which was that individuals with a greater percentage of fast-twitch fibers would demonstrate a greater dietary NO\textsubscript{3}\textsuperscript{−}-induced increase in muscle power. In particular, we found no correlation between the increase in Pmax and V\textsubscript{max} or fatigue index during the placebo trial. Although indirect, numerous previous studies have demonstrated that these (or comparable) measurements are significantly correlated with muscle fiber type (e.g., Coyle et al. 1979; Ivy et al. 1981; McCartney et al. 1983). Moreover, V\textsubscript{max} and fatigue index were highly characteristic of a given subject, as indicated their high intraclass correlation coefficients. Given the strength of the association between muscle fiber type, speed, and fatigability found in previous studies (Coyle et al. 1979; Ivy et al. 1981; McCartney et al. 1983) along with the reproducibility of our measurements and the >2-fold range in V\textsubscript{max} and fatigue index during the placebo trial, it seems unlikely that the lack of correlation of the latter measures with the magnitude of the increase in Pmax with NO\textsubscript{3}\textsuperscript{−} ingestion is the result a type II statistical error. On the other hand, the premise that dietary NO\textsubscript{3}\textsuperscript{−} supplementation selectively targets fast-twitch fibers is based largely on animal studies of muscle blood flow and oxygenation during aerobic exercise, for example, (Ferguson et al. 2015), and is only indirectly supported by human data. Specifically, Bailey et al. (2015) demonstrated dietary NO\textsubscript{3}\textsuperscript{−}-induced differences in muscle oxygenation, whole-body VO\textsubscript{2} kinetics, and performance during cycling when pedaling at 115 rpm but not at 35 rpm. Breese et al. (2013) reported similar benefits during the transition from moderate to high-intensity exercise but not from low to moderate intensity exercise. These data, along with the fact that we have previously reported that NO\textsubscript{3}\textsuperscript{−} improves muscle function only at higher velocities (Coggan et al. 2015a,b), have been interpreted by Jones et al. (2016) as reflecting enhanced recruitment of fast-twitch fibers at a higher velocities/intensities of exercise. It is unclear, however, whether altering pedaling rate in fact changes the pattern of motor unit recruitment (Ahlquist et al. 1992). Similarly, the relationship between exercise intensity and O\textsubscript{2} flux is complex, with motor unit recruitment being only one influencing factor (Jones et al. 2011). Finally, in both fast- and slow-twitch muscle NO seems to improve contractile function by increasing the rate of cross-bridge cycling, not the amount of force per cross-bridge (Maréchal and Gaily 1999). The resultant shift in the force-velocity (and hence power-velocity) curve, and not a selective impact only in fast-twitch fibers, may therefore explain why we have previously observed statistically significant NO\textsubscript{3}\textsuperscript{−}-induced improvements in power only at higher speeds of contraction (Coggan et al. 2015a,b). The notion that dietary NO\textsubscript{3}\textsuperscript{−} affects only, or even primarily, human fast-twitch fibers would therefore still seem equivocal.

An unexpected observation in this study was that, at least in terms of improvements in Pmax, women seem to benefit more than men from dietary NO\textsubscript{3}\textsuperscript{−} intake. Specifically, although not significant in the univariable analyses, female sex was the only predictor other than plasma NO\textsubscript{2}\textsuperscript{−} concentration selected by the stepwise forward regression procedure. Female subjects also tended to be more to likely be “high responders” to NO\textsubscript{3}\textsuperscript{−} supplementation, with five out of seven demonstrating greater-than-

*P < 0.01.
average increases in $P_{max}$. This was true even though $NO_3^-$ intake increased plasma $NO_2^-$ concentration similarly in both women (i.e., +131 ± 162%) and men (i.e., +124 ± 93%). Previous studies of the effects of dietary $NO_3^-$ on exercise performance have included only male subjects (e.g., Christensen et al. 2013; Boorsma et al. 2014; Haider and Folland 2014; Hoon et al. 2014; Bailey et al. 2015; Whitfield et al. 2017), or have not commented on possible sex-related differences (e.g., Breese et al. 2013; Hoon et al. 2015). It has been reported, however, that plasma $NO_3^-$ (Jilma et al. 1996; Ghasemi et al. 2008) and/or breath NO levels (Jilma et al. 1996; Olivieri et al. 2006) are lower in women. The reason for this difference is not known, but it may be due to suppression of NO production by progesterone (Scichilone et al. 2013) and/or a sex-related difference in the distribution of a polymorphism in the neuronal NO synthase (NOS) gene (Grasemann et al. 2003). Regardless, lower NO bioavailability under baseline conditions could explain why the women seemed to be more responsive to dietary $NO_3^-$ intake. Indeed, we have previously observed an approximately twofold greater dietary $NO_3^-$-induced improvement in muscle power in patients with HF (Coggan et al. 2015a) compared to healthy control subjects (Coggan et al. 2015b) or athletes (Rimer et al. 2016), presumably because of diminished NO-mediated NO production (Katz et al. 1999) and enhanced NO destruction (Münzel et al. 2015) in patients with HF. Somewhat along the same lines, Kapil et al. (2010) found that changes in blood pressure in response to $NO_3^-$ ingestion were greatest in individuals with lower baseline plasma $NO_2^-$ concentrations (and higher baseline blood pressures), although in this case it was men who benefited the most. In any case, future studies should more directly address possible sex-related differences in the effects of $NO_3^-$ ingestion on exercise performance.

There are a number of limitations to this study. The most obvious is that muscle biopsies were not performed to directly determine fiber type distribution, which potentially could have revealed a relationship between the percentage of fast-twitch fibers and the relative increase in $P_{max}$. Our study also included a relatively small number of individuals, only two of which were regular exercisers and none of whom were presently competing in endurance sports. Whether similar results would be obtained in a larger group of subjects and/or among athletes therefore cannot be determined from the present data. Although we used a randomized, placebo-controlled, cross-over design, there were no significant order effects, and $P_{max}$, $V_{max}$, and fatigue index proved to be highly reliable, it is possible that inclusion of a familiarization trial would have altered the results (especially in the several subjects in whom $NO_3^-$ ingestion seemed to impair muscle function.

Finally, although we have been able to identify two factors (i.e., plasma $NO_2^-$ concentration and possibly subject sex) contributing to interindividual differences in the effects of dietary $NO_3^-$ on muscle contractile function, it must be emphasized that over half of this variability remains unexplained. Of course, some of this variability represents normal day-to-day variation in human performance (Coggan and Costill 1984), and is not due to $NO_3^-$ ingestion per se. Such random variability, however, could not explain the wide range of responses we observed, and as indicated previously measurement of $P_{max}$ was highly reproducible. Additional studies measuring $NO_3^-$ reduction in the mouth as well as NO/sGC/cGMP/PKG signaling in muscle may provide further insight into the mechanism(s) responsible for this marked interindividual variability in the effects of dietary $NO_3^-$ on muscle power.

In summary, in this study we sought to identify factors influencing the magnitude of the improvement in muscle power due to dietary $NO_3^-$ intake. Our findings indicate that variable increases in NO bioavailability, as indicated by changes in plasma $NO_2^-$ concentration, along with subject sex account for ~40% of this variability. On the other hand, interindvidual differences in muscle fiber type do not appear to be important. Much of the variation in response between individuals remains unexplained.
