Summary

MAP1-family proteins are classical microtubule-associated proteins (MAPs) that bind along the microtubule lattice. The founding members, MAP1A and MAP1B, are predominantly expressed in neurons, where they are thought to be important in the formation and development of axons and dendrites. Mammalian genomes usually contain three family members, MAP1A, MAP1B and a shorter, more recently identified gene called MAP1S. By contrast, only one family member, Futsch, is found in Drosophila. After their initial expression, the MAP1A and MAP1B polypeptides are cleaved into light and heavy chains, which are then assembled into mature complexes together with the separately encoded light chain 3 subunit (LC3). Both MAP1A and MAP1B are well known for their microtubule-stabilizing activity, but MAP1 proteins can also interact with other cellular components, including filamentous actin and signaling proteins. Furthermore, the activity of MAP1A and MAP1B is controlled by upstream signaling mechanisms, including the MAP kinase and glycogen synthase kinase-3 β pathways.

Gene organization and evolutionary history

Various classes of microtubule-associated proteins (MAPs) are expressed in eukaryotic cells. Whereas some MAPs bind specifically to the microtubule plus ends or the minus ends (centrosomes), many MAPs bind along the microtubule lattice. The latter category includes both enzymatically active MAPs, such as microtubule motors or the microtubule-severing protein katanin, and structural MAPs such as the MAP2/tau or stable tubule only (STOP) protein families. This article focuses on the classical, microtubule-lattice-binding structural MAPs in the MAP1 family, which are best known for their microtubule-stabilizing activity. Most knowledge on MAP1-family proteins has been derived from studies in rodents and, unless noted otherwise, insights from rodents are expected to apply for mammalian family members in general. The MAP2/tau family of classical MAPs is encoded by distinct, apparently unrelated genes and has been reviewed in an earlier issue of Genome Biology [1].

Most vertebrate genomes (including human, mouse and rat) contain three family members, MAP1A, MAP1B and MAP1S, which are encoded by separate genes (see Table 1 for chromosomal locations of the human genes) [2,3,4]. The shortest MAP1 protein, MAP1S, is also known as VCY2IP1 or C19ORF5. A search for proteins with sequence similarity to MAP1A or MAP1B proteins (summarized in Figure 1a) shows that there are three apparent MAP1 family members in bony fish (L.D. and S.H., unpublished observations), but the functional significance of these isoforms is unclear. Fish MAP1-family proteins have been reported to be only about 25% of the size of their mammalian counterparts [5]. No obvious ortholog of any MAP1-family protein is present in Caenorhabditis elegans or more primitive organisms, but a single protein related to MAP1A and MAP1B, called Futsch, can be found in Drosophila melanogaster [6]. Futsch differs from vertebrate MAP1A and MAP1B isoforms in that it contains a repeated central domain with homology to vertebrate...
neurofilaments [6]. As classic neurofilaments are absent from the Drosophila genome, it may be that Futsch is an ancestral precursor of neurofilament proteins.

Vertebrate MAP1-family genes span multiple exons. Alternative splicing has been reported only in mammalian MAP1B genes [3]; its functional relevance is unclear. Sequence similarity between distinct MAP1-family proteins in an individual organism is most prominent in the extreme amino and carboxyl termini (approximately 85% similarity at the amino-acid level). Sequences with significant similarities are also found in Drosophila Futsch (approximately 60% similarity to rat MAP1A or MAP1B), but it is not clear from this information whether the Drosophila protein is an ortholog of either MAP1A or MAP1B (Figure 1a).

An accessory protein chain that can be found in MAP1A and MAP1B protein complexes is derived from the LC3 gene encoding MAP1 light chain 3 [7]. LC3 and related proteins do not show significant sequence similarity to MAP1A or MAP1B and are not usually considered to be part of the MAP1 protein family. At least seven distinct LC3-related genes are found in humans (Table 1, Figure 1b), and various orthologs of these genes are found in both highly developed and simpler eukaryotes. LC3-related genes are related to the yeast ubiquitin-like gene AUT7 (ATG8) [8] and are thought to play a role in autophagy. One LC3-related gene has been predicted in archaea (hypothetical protein ST0261 in Sulfolobus tokodaii). No orthologs of the MAP1 and LC3 families are found in prokaryotes.

### Characteristic structural features

The MAP1A, MAP1B and MAP1S polypeptides are each translated as larger proteins that are then processed by proteolytic cleavage near the carboxyl terminus, leading to the generation of heavy chains (MAP1A-HC of 350 kDa, MAP1B-HC of 300 kDa and MAP1S-HC of 100 kDa) and light chains (LC2 of 28 kDa from MAP1A, LC1 of 32 kDa from MAP1B and MAP1S-LC of 26 kDa) [4,9,10]. The light chains generated by MAP1A (LC2) and MAP1B (LC1) can interact with both MAP1A and MAP1B heavy chains [11]. For MAP1B, light-chain binding has been mapped to a 120 kDa fragment within the amino terminus of the heavy chain [10]. LC3 can also interact with the MAP1A and MAP1B heavy chains [7]. The exact stoichiometric composition of MAP1A and MAP1B heavy and light chains has not been determined, but in the case of MAP1B, a ratio of MAP1B-HC:LC1:LC3 of 1:2:0.2 has been estimated [12].

All four light chains can bind microtubules by themselves [4,7,13], and the MAP1A and MAP1B heavy chains both contain additional sequences that bind microtubules (Figure 2) [14-17]. Amino acids within these microtubule-binding domains are diverse, including both positively and negatively charged residues. Interestingly, the MAP1B heavy chain was found to suppress the microtubule-binding activity of its light chain [18]. For MAP1A, the contributions of the heavy and light chains for microtubule binding are less clear. In kangaroo PtK2 cells, exogenously expressed MAP1A light chain (LC2) was sufficient by itself to bind and stabilize microtubules [13]. In contrast, in green monkey COS7 cells, both MAP1A light and heavy chains were required [19].

| Protein                  | Gene locus     | Predicted number of exons | Alternatively spliced exons * |
|--------------------------|----------------|---------------------------|------------------------------|
| MAP1-family proteins     |                |                           |                              |

*The numbers given are the exon numbers that are either included (+) or excluded (-) from an alternatively spliced variant.
In addition to microtubule-binding activity, the MAP1A, MAP1B and MAP1S light chains can also bind filamentous actin (F-actin) [4,13,18]. The microtubule- and F-actin-binding sites on the MAP1A and MAP1B light chains map to different sequence regions. Microtubule binding is confined to the amino terminus of the light chains, and a direct F-actin interaction has been localized to the carboxyl terminus. Furthermore, an exogenous carboxy-terminal fragment of MAP1A and MAP1B light chains colocalized with F-actin in stress fibers of non-neuronal cells [13,18]. It is yet not known if a single MAP1 unit can bind both cytoskeletons at the same time and thus crosslink the two cytoskeletons.

Structural details about MAP1-family proteins are largely unknown. Both microtubule and F-actin binding have been mapped to regions of about 120 amino acids in the MAP1B light chain, but no further structural details or critical amino-acid residues related to these interactions have been identified. The only structural data available are derived from electron microscopy of preparations treated by the rotary shadowing technique. These studies suggest that MAP1A is a flexible, elongated protein [20], whereas MAP1B appears to be a rod-shaped, elongated molecule with a terminal, round globular domain [21]. No information about secondary structures in either molecule is available. Moreover, predictions suggest that mammalian MAP1A and MAP1B and Drosophila Futsch are natively unfolded (L.D. and S.H., unpublished observations; predictions were calculated using FoldIndex [22]). Although over 50% of their entire protein sequences are predicted to be unstructured, some folded regions might exist in the extreme amino termini of the heavy chains.

**Localization and function**

MAP1 family members and their splice variants have specific regional and temporal expression patterns in the nervous
system. MAP1B is highly expressed during early neuronal development and gradually diminishes during maturation [23]. In developing cultured neurons, MAP1B protein is localized to axons, as well as their precursors (so-called ‘minor neurites’) [24]. Furthermore, MAP1B is especially enriched in growing axons [23,24]. MAP1A is predominantly expressed in adult neurons, where it localizes preferentially to dendrites [11]. MAP1S is expressed in various tissues including mouse brain [4].

**Functions of MAP1A and MAP1B in the nervous system**

MAP1A and MAP1B were originally discovered because of, and were characterized by, their ability to bind and stabilize microtubules. Ultrastructural analysis revealed the presence of these MAPs along the sides of microtubules [20,21]. *In vitro* studies suggested that the microtubule-stabilizing activity of MAP1B is weaker than that of the distinct neuronal microtubule stabilizer MAP2 [25]. This could be a consequence of factors such as differential phosphorylation or the recently documented inhibition of microtubule-stabilizing activity of MAP1B light chain by its heavy chain [18]. Overexpression of MAP1B in heterologous cell systems induces the formation of microtubule bundles with a ‘wavy’ appearance [13]. In contrast, microtubule bundles induced by MAPs of the MAP2/tau family are straight and rigid [26,27]. Evidence for direct crosslinking of microtubules by MAP1A and MAP1B is lacking, leaving open a potential role for adapter proteins.

Complete removal of the *MAP1B* gene results in the absence of the corpus callosum [28], a brain region mostly composed of axons that cross the midline, suggesting that certain
Axonal growth mechanisms are disturbed. More recently, enhanced neurite branching and impaired axonal turning behavior were reported in regenerating adult mouse dorsal root ganglion neurons lacking MAP1B [29]. Earlier reports of various knockout lines in which only portions of the MAP1B gene were removed described either more severe [30,31] or less severe [32] phenotypes, presumably owing to different genetic backgrounds or different alternatively spliced MAP1B isoforms.

Interestingly, functional redundancy of MAP1B with both MAPs of the MAP2/tau family has been reported [33-35]. Simultaneous inhibition of MAP1B and either MAP2 or tau resulted in more severe phenotypes than single knockouts. Taken together, these experiments suggest a role for MAP1B, tau and MAP2 in both neuronal migration and process outgrowth. Knockout studies of the MAP1A and MAP1S genes have not been reported to date. Other classes of MAPs have functions that at least partially overlap with those of the MAP1 and MAP2/tau families: proteins such as STOP, adenomatous polyposis coli (APC), doublecortin, or spectraplakins might provide additional redundancy in MAP function.

**Role of MAP1A and MAP1B as adaptor proteins**

The MAP1-family proteins have been shown to interact with numerous proteins and specific functions have been proposed for some of these interactions. For example, MAP1A is found in postsynaptic densities (PSDs), where it interacts with PSD-95. This interaction might be functionally important: mutations that reduce the MAP1A-PSD95 interaction confer sensitivity to hearing loss induced by a mutation in the *tub* gene, a condition that is proposed to involve defects in synaptic function [36]. More recently, the interaction between MAP1B and the disease-related protein gigaxonin has been suggested to be critically involved in the progression of giant axonal neuropathy, a human neurodegenerative disease [37]. Table 2 provides an overview of identified interaction partners and briefly describes the proposed function of each interaction.

### Table 2

**Interaction partners of MAP1-family proteins**

| Interacting protein* | Proposed function of the interaction | References |
|----------------------|-------------------------------------|------------|
| **MAP1A** Microtubules | Stabilization of microtubules | [14,13,17] |
| F-actin | Integration of microtubule and F-actin cytoskeletons | [13] |
| EPAC | Enhancement of Rap1 GTPase activity and cell adhesion | [42] |
| DISC1 | Linking of DISC1 to microtubules; pathogenesis of schizophrenia | [43] |
| PSD-93 | Linking of PSD-93 to microtubules | [44] |
| CK1δ | Interaction with and phosphorylation of the MAP1A light chain LC2 in vitro | [45] |
| BKCa potassium channel | Association of the channel with the cytoskeleton | [46] |
| **MAP1B** Microtubules | Stabilization of microtubules | [13,15,16,47] |
| F-actin | Integration of microtubule and F-actin cytoskeletons | [13,18,48] |
| Mapmodulin | Modulation of neurite extension | [49] |
| Gigaxonin | Enhanced stabilization of microtubules by MAP1B; control of MAP1B light chain degradation; potential role in giant axonal neuropathy | [37,50] |
| Myelin-associated glycoprotein | Enhanced MAP1B expression and phosphorylation | [51] |
| GABA(C) receptor | Linking of GABA(C) receptors to the cytoskeleton | [52] |
| FMRI | Interaction with MAP1B mRNA and repression of its translation | [53] |
| ee3 | Alteration of the stability or folding of ee3 | [54] |
| LIS1 | Interference with the LIS1-dynein interaction | [55] |
| GRIP1 | Localization of AMPA receptors to synaptic sites | [56] |
| **LC3** Microtubules | Regulation of the microtubule binding of MAP1A and MAP1B | [6] |
| Calmodulin | Transduction of calcium signals | [57] |
| **MAP1S** Microtubules | Stabilization of microtubules | [4] |
| F-actin | Integration of microtubule and F-actin cytoskeletons | [4] |
| RASSF1A | Regulation of mitotic progression | [58,59] |

*Abbreviations: EPAC, exchange protein directly activated by cAMP; DISC1, disrupted-in-schizophrenia 1; PSD-93, postsynaptic density-93; CK1δ, casein kinase I delta; BKCa, large-conductance Ca2+-dependent K+ channel; GABA, gamma-aminobutyric acid; FMRI, Fragile X mental retardation 1; ee3, orphan G-protein coupled receptor; LIS1, lissencephaly-related protein 1; AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; GRIP1, glutamate receptor interacting protein 1; RASSF1A, Ras association domain family 1A.
Mechanism and regulation

Microtubules exhibit dynamic instability, an intrinsic behavior characterized by alternating phases of growth, shortening and pausing. MAP1A and MAP1B proteins bind along the length of microtubules and are thought to stabilize microtubules by altering this dynamic behavior. One study suggests that MAP1B mediates microtubule stabilization specifically by reducing depolymerization rates [25].

Phosphorylation of MAP1B by glyogen synthase kinase-3 β (GSK3β) has been extensively studied both in vitro and in vivo. Phosphorylation by this kinase has been mapped to two residues, Ser1260 and Thr1265, which are specifically phosphorylated in growing axons [38]. Furthermore, in contrast to the microtubule-stabilizing effect of unphosphorylated MAP1B, GSK3β-phosphorylated MAP1B sensitizes microtubules to depolymerizing agents [39]. Taken together, such experiments lead to the idea that MAP1B’s phosphorylation state might regulate microtubule stability in growing axons, and thereby influence axonal growth.

Recent evidence also links the Jun N-terminal kinase (JNK) pathway to phosphorylation of MAP1B [40]. Less is known about MAP1A, but a recent study suggests that activity-dependent dendritic remodeling through the mitogen-activated protein (MAP) kinase pathway is dependent on MAP1A [41]. Very little is known about the mechanism and regulation of MAP1S.

Frontiers

Two decades after their original discovery, many functions of MAP1A and MAP1B have been uncovered in vitro and in vivo. Knockout animals and functional assays suggest specific roles of MAP1A family members in both the development and the degeneration of the nervous system. Structural details of MAP1-family proteins are largely unknown, however, and apparent functional redundancies and cross-talk with other MAPs and cytoskeletal regulators make it difficult to pinpoint the exact function(s) of individual MAPs in vivo. Furthermore, the variety of upstream regulatory pathways and downstream effectors provide a major challenge to fully understanding MAP1A and MAP1B function. Fortunately, certain key pathways controlling MAP1A and MAP1B activity have been identified, although little is yet known about MAP1S. A broader and more precise analysis of phosphorylation and other posttranslational modifications still needs to be carried out, however, in order to fully understand MAP1A and MAP1B function in signaling networks controlling neuromorphogenesis.
