Particle propagation

in a random\&quasiperiodic potential

Abstract: We numerically investigate the Anderson transition in an effective dimension

\(d\ (3 \leq d \leq 11)\) for one particle propagation in a model random\&quasiperiodic potential. The found critical exponents are different from the standard scaling picture. We discuss possible reasons for this difference.

PACS numbers 71.55.Jv, 05.45.+b
The Anderson transition has been intensively investigated during last years. According to the scaling theory for spinless particles all states are localized for dimension \( d \leq 2 \), while a transition from localization to diffusive propagation occurs for \( d > 2 \) when a certain hopping parameter \( k \) crosses a critical value \( k_{cr} \) (see reviews \[1, 2\]). The one parameter scaling theory predicts that in the localized phase \( (k < k_{cr}) \) the typical localization length of wavefunctions diverges at the critical point as \( l \sim |k - k_{cr}|^{-\nu} \). Above the critical point the dynamics is diffusive and the DC conductivity \( \sigma \) which is proportional to the diffusion rate \( D \) is assumed to approach zero at the critical point as \( \sigma \sim D \sim |k - k_{cr}|^s \). Scaling arguments give the following relation between the exponents: \( s = (d - 2)\nu \). For dimension \( d = 2 + \epsilon \) the \( \epsilon \) expansion theory predicts \( s = \nu = 1 + O(\epsilon^4) \)[3]. In higher dimensions the problem was studied by many authors \[4, 5, 6\]. According to the results presented there \( \nu = 1/2 \) for \( d \to \infty \) while for the delocalized phase \( s \approx d/2 \)[6] or \( \sigma \) decreases exponentially near the transition[4].

Numerical investigations of the exponents has been restricted to \( d = 3 \) where it was found \( s = \nu = 1.5 \pm 0.1 \)[4 and refs. therein] in agreement with the scaling relation between \( \nu \) and \( s \). However, the applied numerical methods were quite heavy and did not allow to obtain a better accuracy in the determination of the exponents or to increase the dimension. For \( 2 < d \leq 3 \) and \( d = 4 \) there are only recent results for \( \nu \)[7] obtained by transfer matrix technique. While the results there seem to be in agreement with the scaling theory the system size was so small that the question if the thermodynamic limit had been reached remains open.

An effective way to increase the number of dimensions was proposed in [8] and applied
for investigation of transition in $d = 3$ \[9\] where it was also found $s \approx 1.25$ and $\nu \approx 1.5$.

The method consists in the investigation of the well known model of quantum chaos namely the kicked rotator model with a frequency–modulated amplitude of kicks. The time–dependent Hamiltonian of the model is given by:

$$H = H_0(\hat{n}) + V(\theta, t)\delta_1(t)$$  \hspace{1cm} (1)

where $\delta_1(t)$ is the periodic delta function with period 1 between kicks, $\hat{n} = -i\partial/\partial\theta$ and $\theta$ is a periodic angle variable. $H_0$ determines the spectrum of unperturbed energies $E_n$ chosen randomly distributed in $(0, 2\pi)$. The perturbation $V$ depends on time in a quasi periodic way:

$$V(\theta, t) = -2\tan^{-1}(2k(\cos \theta + \sum_{j=1}^{d-1} \cos(\theta_j + \omega_j t)))$$  \hspace{1cm} (2)

with $d - 1$ incommensurate frequencies $\omega_j$. Here $\theta_j$ are initial phases and the time is measured in number of kicks. The Hamiltonian \[1\] can be re–written in the extended phase space by letting $\hat{n}_j = -i\partial/\partial\theta_j$. After that the problem becomes periodic in time and the eigenvalues equation for the quasi-energy eigenfunctions can be mapped to the usual solid–state form \[10, 9\]:

$$T_n u_n + k \sum_{r} u_{n-r} = 0$$  \hspace{1cm} (3)

where the $\sum'$ indicates a sum over the nearest neighbors to $n$ on a $d$–dimensional lattice and

$$T_n = -\tan(1/2(E_n + \sum_{j=1}^{d-1} \phi_j + \lambda))$$  \hspace{1cm} (4)
Here $\phi_j = n_j \omega_j$ and $\lambda$ is the quasi-energy. If $\phi_j$ are randomly distributed in $(0, 2\pi)$ then Eq. (3) becomes equivalent to the Lloyd model at the center of the band ($E = 0$). The parameter $\lambda$ determines only the phase shift and it is clear that the physical characteristics are independent on its value. Since the mapping between (1) and (3) is exact, it is possible to study the Anderson transition in $d$-dimensions by investigating the dynamics of the 1-dimensional system (3). This gives an effective gain of order $N^{d-1}$ in numerical computations if $N$ is the system size. Finally, discussing the model, we should mention that the presence of disorder in the expression for $T_n$ is crucial. Indeed, according to the exact mathematical results [11] in the case of pure quasiperiodic potential when in (4) $E_n = \omega n$ all states for typical irrational frequencies are exponentially localized for any $d$.

The physical meaning of this result is quite clear: the classical dynamics in this case is integrable and variation of unperturbed actions (levels $n$) is restricted by invariant curves. However, even if only in one direction the dispersion becomes nonlinear then the classical dynamics can become chaotic with diffusive spreading in all $n$ directions. In this paper we investigate how this diffusion is affected by quantum effects.

Using the above approach we studied numerically the Anderson transition for integer $3 \leq d \leq 11$ in the model (1) - (2). The choice of frequencies was the following: for $d = 3$ we fixed $\omega_{1,2}/2\pi = 1/\lambda, 1/\lambda^2$ with $\lambda = 1.3247...$ being the real root of the cubic equation $x^3 - x - 1 = 0$ which gives the most irrational pair [9]; for $d = 4$ we added $\omega_3/2\pi = 1/\sqrt{2}$ and for $d > 4$ we chose all frequencies randomly in the interval $(0, 2\pi)$. The size of the basis $N$ was between 1024 and 4096. The total number of iterations (kicks) was usually around $10^6$ but in some cases close to the critical point the evolution
was followed up to $10^7$ kicks. We used from 10 to 100 realizations of disorder to suppress statistical fluctuations.

A typical example of diffusive spreading over the lattice for $d = 4$ is shown in Fig.1. Here $k > k_{cr}$ and the second moment of the probability distribution grows linearly with time. At the same time the probability distribution over levels has the gaussian shape (see Fig. 1b). This allows to determine the diffusion constant $D$. Usually, we extract it from the probability distribution since here the statistical fluctuations are lower than for the value obtained from the second moment $D = n^2/t$. However, both methods give quite close values. The value of $D$ found in this way is then averaged over different realizations of disorder. For $k < k_{cr}$ the probability distribution averaged in time reaches a stationary exponentially localized form and at the same time the growth of the second moment $n^2$ is saturated (Fig.2). From the obtained stationary distribution the localization length is determined in the two ways. One is by the square list fitting of $\ln |\psi_n|^2 = -2\gamma n + b$ with the localization length being $l = 1/\gamma$ and $b$ some constant [12]. Another definition is via the participation ratio so that $\gamma_i = \sum_n |\psi_n|^4/\sum_n |\psi_n|^2$. After that both values $\gamma$ and $\gamma_i$ were averaged over different realizations of disorder. The inverse participation ratio $1/\gamma_i$ determines another length scale which in principle can be parametrically different from $l$.

The numerical results for the dependence of $D, \gamma$ and $\gamma_i$ on parameter $k$ for the effective dimension $d = 3$ are presented in Figs. 3,4. To determine the scaling near the critical point we used the 3 parameter fit of the type $\gamma(i) = \gamma_0 |k - k_{cr}|^\nu$ and $D = D_0 |k - k_{cr}|^s$. The results of the fitting are given in the figures captures (see also Table 1) as well as the parameters of $\chi^2$ test. Formally the statistical error of the exponents $s, \nu$ found in this
way is rather small (less than 1% of the value). However, the estimate of non-statistical errors is quite difficult since the fitting procedure is rather sensitive to the value of $k_{cr}$.

From comparison of $k_{cr}$ values obtained from diffusive and localized phases it can be estimated on the level of 5%. The values of the exponents for $D$ and $\gamma_i$ are in the good agreement with the results of [9] (see also [12]). Our data indicate significant difference for the exponents $\nu$ defined via $\gamma$ and $\gamma_i$ for $d = 3$. To demonstrate the dependence near the critical point we fixed the value of $k_{cr}$ defined from Fig. 3 and show the behaviour in log-log scale near $k_{cr}$ in Fig.4. The two parameter fit with fixed $k_{cr}$ shown in Fig.4 gives similar values of the exponents $s, \nu$ as in the case of Fig.3. The linear dependence of $\ln \gamma, \ln D$ on $\ln |1 - k/k_{cr}|$ describes quite well the variation of localization length and diffusion in one/two orders of magnitude.

The case with the dimension $d = 4$ was investigated in a similar way. The results are presented in Figs. 5,6. They definitely show stronger deviation from the scaling relation between exponents $\nu, s$. Especially pronounced is the small value of $s$ which remains less than 2.

Inspite of this deviation from the scaling relation the behaviour at the critical point is close to the standard expectations [1, 2, 3, 4, 5, 6]. Indeed, at $k_{cr}$ the conductance has a finite critical value $g^*$. From another side $g \sim E_c/\Delta$ where $E_c \sim D/L^2$ is the Thouless energy, $D$ is the diffusion coefficient and $\Delta \sim B/L^d$ is the level spacing in a block of size $L$ with $B \sim 1$ being the band width. Therefore, at $k_{cr}$ one has $D \sim Bg^*/R^{d-2}$ where $R \sim L$ is a typical length scale. At the same time $D = R^2/t$ so that finally $R^d \sim Bg^*t$.

Our numerical data for the values of $k$ close to $k_{cr}$ (Figs.7,8) show that this relation
works. Formal fits give $R^d \sim t^{\alpha}$ with $\alpha = 1.13(d = 3), 1.12(d = 4)$ close to the expected value. We also analyzed the decay of the average probability to stay at the origin $n_0$: 

$$P_0(T) = \frac{1}{T} \int_0^T dt |\psi_{n_0}(t)|^2.$$ 

As can be seen in Figs 7b,8b it is characterized by a power law decay. The numerically obtained values of the power are not far from $1/d$ (Figs. 7,8). This indicates that multifractal exponents are relatively small. This fact is also confirmed by the rescaling of the probability distribution $f_n = |\psi_n|^2$ at different moments of time (Fig.9). It shows that after rescaling $t^{1/d} f_n$ and $n/t^{1/d}$ the distribution remains approximately stationary in time, being however not exactly exponential.

We also investigated the delocalization transition for $d = 5, 11$ (Figs. 10, 11). From the localized side the transition was very sharp (very large $\gamma_0$) and it is not clear how accurate are the critical exponents obtained in this region even if the formal statistical error is quite small. Namely, the fits for $\gamma$ in the localized phase give $\gamma_0 = 257(28), k_{cr} = 0.214(1), \nu = 2.32(4)$ with $\chi^2 = 0.18$ at $d = 5$ and $\gamma_0 = 2115(181), k_{cr} = 0.107(2), \nu = 2.55(2)$ with $\chi^2 = 0.04$ at $d = 11$. However, from the diffusive side the transition is going in a rather smooth way with the exponent $s$ close to 2 being quite different from the expectations of scaling theory (see Figs. 10,11). The values of the exponents for different dimensions are presented in the Table 1. It definitely shows that the scaling relation $s = (d - 2)\nu$ does not work at all. Contrary to that our numerical data indicate that for $d \gg 1$ the exponent $s$ approaches to its limiting value $s \approx 2$. Finally, let us mention that the dependence of $k_{cr}$ on $d$ is quite close to $k_{cr} \approx 1/d$. This type of behaviour can be expected since in the kick potential all frequencies are mixed only if $k \sum_{j=1}^d \cos(\omega_j t) \sim k_{cr} d \sim 1$.

In conclusion, we studied the Anderson transition in a model random & quasiperiodic
potential with effective dimension $d \geq 3$. This model demonstrates quite many features which are the same as for the standard Anderson transition in a disordered $d$-dimensional potential. For $d = 2$ all states are localized and the localization length grows exponentially with the decrease of disorder \[8\]. For $d = 3$ the model has a transition from localization to diffusion with the critical exponents close to expected \[9\]. However, for higher dimensions the exponents strongly deviate from the expected scaling relation $s = (d - 2)\nu$. Contrary to that our numerical data show that for $d \gg 1$ one has $s \approx 2$. It is possible to give the following argument supporting $s = 2$. For $d \gg 1$ the critical value of the coupling goes to zero $k_{cr} \sim 1/d$. Therefore, the change of action is governed by the equation

$$\partial n / \partial t \approx k \sin \theta \sum_{j=1}^{d} \cos \omega_j t$$

(5)

For $d$ going to infinity this sum gives the real diffusive process in which $n^2 \sim k^2 t \sim Dt$. Due to that it is in some sense natural to expect that asymptotically for $d \gg 1$ the exponent $s$ approaches to 2. However, further investigations are required to conclude whether the behaviour of the scaling exponents is or isn’t a peculiarity of the model under investigation. In our opinion, for the classical model chaos and diffusion in all directions can appear even if the motion is nonlinear only in one direction. Due to that we think that the quantum dynamics of the above model should be quite similar to a real disordered system in dimension $d$.

We thank V. Kravtsov for useful discussions. One of us (F.B.) is very grateful to the Laboratoire de Physique Quantique, UMR C5626 du CNRS, Univ. P. Sabatier, for the hospitality extended to him during his visit when this work has been started and another (D.L.S.) thanks the University at Como for hospitality during different stages of this work.

[12] Let us mention that in Ref.9 it was chosen $b = \ln \gamma$. This choice enhances the con-
tribution of the states near the maximum at $n = 0$ so that $\gamma$ defined in this way
becomes close to the definition of $\gamma$ via the participation ratio $\gamma_i$.

Figure 1: (a) Behaviour of the second moment on time for $k = 0.33$, $d = 4$ (diffusive side). Dashed line is the fitted diffusion coefficient $D = 0.0205$. Fourier basis is $N = 1024$. (b) Logarithm of the averaged distribution function between $t = 0.995 \cdot 10^6$ and $t = 10^6$ ($t=$number of kicks). Full line is the best fit gaussian which gives a diffusion coefficient $D = 0.0229$. On x-axis we put $n^2$.

Figure 2: (a) Behaviour of the second moment on time for $k = 0.24$, $d = 4$ (localized side). Basis is $N = 1024$. (b) Logarithm of the averaged distribution function between $t = 0.3995 \cdot 10^7$ and $t = 0.4 \cdot 10^7$. On x-axis we put $n$. Line represents the fitted localized distribution with $l = 15.4$.

Figure 3: Inverse localization length (left side) and diffusion rate (right side) for $d = 3$. Lines are the separate fits: $\gamma = \gamma_0(k_{cr} - k)^\nu$ with $\gamma_0 = 8.01(1)$, $k_{cr} = 0.509(1)$ and $\nu = 2.37(1)$ with $\chi^2 = 10.5$ and $D = D_0(k - k_{cr})^s$ with $D_0 = 2.56(2)$, $k_{cr} = 0.479(1)$ and $s = 1.25(1)$ with $\chi^2 = 32.6$. A similar fit for $\gamma_i = \gamma_0i(k_{cr} - k)^{\nu_i}$ gives $\gamma_0i = 3.7(3)$, $k_{cr} = 0.489(4)$, $\nu_i = 1.71(6)$ and $\chi^2 = 15.4$. Here $10 - 100$ random configurations have been iterated up to $10^7$ kicks. Data errors are within the symbol size.
Figure 4: $d = 3$. (a) Logarithm of diffusion rate vs $\ln(k/k_{cr} - 1)$ where $k_{cr}$ is extracted from the separate fit (Fig.3). Straight line is the best fit line with slope $s = 1.248(5)$ and $\chi^2 = 10.6$. (b) Logarithm of the inverse localization length vs $\ln(1 - k/k_{cr})$ where $k_{cr}$ is extracted from the separate fit (Fig.3). Straight line is the best fit line with slope $\nu = 2.374(9)$ and $\chi^2 = 33.8$. (c) Logarithm of the participation ratio $\gamma_i$ vs $\ln(1 - k/k_{cr})$ where $k_{cr} = 0.489(4)$ is extracted in a similar way from a three parameter fit. Here the straight line has slope $\nu_i = 1.71(6)$ and $\chi^2 = 16.3$ Here $10 - 100$ random configurations have been iterated up to $10^7$ kicks. Errors are within the symbol size.

Figure 5: Inverse localization length (left side) and diffusion rate (right side) for $d = 4$. Lines are the separate fits: $\gamma = \gamma_0(k_{cr} - k)^\nu$ with $\gamma_0 = 66.10$, $k_{cr} = 0.306(2)$ and $\nu = 2.53(1)$ with $\chi^2 = 10.2$ and $D = D_0(k - k_{cr})^s$ with $D_0 = 2.29(2)$, $k_{cr} = 0.283(3)$ and $s = 1.52(5)$ with $\chi^2 = 111$. A similar fit for $\gamma_i = \gamma_{0i}(k_{cr} - k)^{\nu_i}$ gives $\gamma_{0i} = 85(28)$, $k_{cr} = 0.305(5)$, $\nu_i = 2.59(2)$ and $\chi^2 = 4.5$. Here $10 - 100$ random configurations have been iterated up to $10^7$ kicks. Data errors are within the symbol size.
Figure 6: $d = 4$. (a) Logarithm of diffusion rate vs $\ln(k/k_{cr} - 1)$ where $k_{cr}$ is extracted from the separate fit (Fig.5). Straight line is the best fit line with slope $s = 1.519(4)$ and $\chi^2 = 115$. (b) Logarithm of the inverse localization length vs $\ln(1 - k/k_{cr})$ where $k_{cr}$ is extracted from the separate fit (Fig 5). Straight line is the best fit line with slope $\nu = 2.534(5)$ and $\chi^2 = 91.81$. (c) Logarithm of the participation ratio $\gamma_i$ vs $\ln(1 - k/k_{cr})$ where $k_{cr} = 0.305(5)$ is extracted in a similar way from a three parameter fit. Here the straight line has slope $\nu_i = 2.59(2)$ and $\chi^2 = 4.5$ Here $10 - 100$ random configurations have been iterated up to $10^7$ kicks. Errors are within the symbol size.

Figure 7: $d = 3$ Study near the critical point at $k=0.48$. (a) Behaviour of $R^d = \sum_n |n|^d |\psi_n|^2$ in time. Best fit (dashed line) gives $R^d \sim t^{1.13(3)}$. (b) Behaviour of the logarithm of the integrated probability to stay $P_0(T)$ as a function of the logarithm of time $T$. Here is $P_0(T) = \frac{1}{T} \int_0^T dt |\psi_{n_0}(t)|^2$ and the initial state vector is $\psi(t = 0) = \delta_{n,n_0}$. Best fit (dashed line) gives $P_0(T) \sim T^{-0.28(3)}$. One random configuration has been considered. Basis is $N=4096$.

Figure 8: The same as Fig.7 but for $d=4$ near the critical point at $k=0.27$. Results from fit gives $R^d \sim t^{1.12(3)}$ and $P_0(T) \sim T^{-0.26(3)}$
Figure 9: Rescaling of the distribution function in the critical region \((k = 0.27)\) for \(d = 4\). (a) The averaged (over \(10^4\) kicks) probability distribution over the unperturbed basis \(f_n\) taken at three different times \(t_1, 2 t_1, 3 t_1\) where \(t_1 = 10^6\), shows that as the time goes on the distribution increases its size. (b) The same as (a) but in the rescaled variables \(t^{1/d} f_n\) and \(n/t^{1/d}\) (since at the critical point \(|n|^d \sim t\) with \(d = 4\)).

Figure 10: \(d = 5\). (a) Diffusion rate vs \(k\), 3 parameters fit (full line) gives: \(D = 2.56(6) (k - .180(2))^{2.04(3)}\) with \(\chi^2 = 36.1\); (b) logarithm of diffusion rate vs \(\ln(k/k_{cr} - 1)\) where \(k_{cr}\) is extracted from (a). Best fit (full line) has the slope \(s = 2.039(9)\)

Figure 11: \(d = 11\). (a) Diffusion rate vs \(k\), 3 parameters fit gives: \(D = 1.35(1) (k - .0924(5))^{1.87(1)}\) with \(\chi^2 = 310\); (b) logarithm of diffusion rate vs \(\ln(k/k_{cr} - 1)\) where \(k_{cr}\) is extracted from (a) Best fit (full line) has the slope \(s = 1.99(5)\)
$d = 3$
