An important and incompletely answered question is whether a closed quantum system of many interacting particles can be localized by disorder. The time evolution of an initially unentangled state is studied for a random-field XXZ Hamiltonian. Interactions induce a dramatic change in the propagation of entanglement and a smaller change in the propagation of particles. For even weak interactions, when the system is thought to be in a many-body localized phase, entanglement shows neither localized nor diffusive behavior but grows without limit in an infinite system: interactions act as a singular perturbation on the localized state with no interactions. The significance for proposed atomic experiments is that local measurements will show a large but non-thermal entropy in the many-body-localized state, which develops over a diverging time scale as in glassy systems.

One of the most remarkable predictions of quantum mechanics is that an arbitrarily weak random potential is sufficient to localize all energy eigenstates of a single particle moving in one dimension [1,2]. In experiments on electronic systems, observation of localization is limited to low temperatures because the interaction of an electron with its environment results in a loss of quantum coherence and a crossover to classical transport. Recent work has proposed that, if there are electron-electron interactions but the electronic system is isolated from other degrees of freedom (such as phonons), there can be a “many-body localization transition” even in a one-dimensional system for which all the single-particle states are localized [3–7].

Progress in creating atomic systems where interactions between particles are strong but the overall many-atom system is highly phase coherent [8] suggests that this many-body localization transition may be observable in experiments [9]. Many-body localization is connected to the problem of thermalization in closed quantum systems as a system cannot thermalize if localization prevents equilibration of energy or particle number.

The goal of the present work is to show that the many-body localized phase differs qualitatively, even for weak interactions, from the conventional, non-interacting localized phase. The evolution of two quantities studied, the entanglement entropy and particle number fluctuations, show logarithmically slow evolution more characteristic of a glassy phase; however, the long-term behavior of these quantities is quite different. The growth of the entanglement entropy has previously been observed [10,11] to show roughly logarithmic evolution for smaller systems and stronger interactions. We seek here to study this behavior systematically over a wide range of time scales, showing that the logarithmic growth begins for arbitrarily weak interactions and does not saturate in the thermodynamic limit, and obtain additional quantities that distinguish among possible mechanisms. We use matrix-product-state methods as well as exact diagonalization; the former allows some, not all, quantities to be computed for larger system sizes.

One-dimensional $s = \frac{1}{2}$ spin chains are a natural place to look for many-body localization [4]. To start, consider the XX model with random $z$-directed magnetic fields so that the total magnetization $S^z$ is conserved:

$$H_0 = J_\perp \sum_i (S_i^x S_{i+1}^x + S_i^y S_{i+1}^y) + \sum_i h_i S_i^z.$$  \hspace{1cm} (1)

Here the fields $h_i$ are drawn independently from the interval $[-\eta, \eta]$. The eigenstates are equivalent via the Jordan–Wigner transformation to Slater determinants of free fermions with nearest-neighbor hopping and random on-site potentials; particle number in the fermionic representation is related to $S^z$ in the spin representation, so the $z$-directed magnetic field is essentially a random chemical potential. Now every single-fermion state is localized by any $\eta > 0$, and the dynamics of this spin Hamiltonian are localized as well: a local disturbance at time $t = 0$ propagates only to some finite distance (the localization length) as $t \rightarrow \infty$. As an example, consider the evolution of a randomly chosen $S^z$ basis state. The coupling $J_\perp$ allows “particles” (up spins) to move, and entanglement entropy to develop, between two sub-regions $A$ and $B$. But the total amount of entanglement entropy generated remains finite as $t \rightarrow \infty$ (Fig. 1), and the fluctuations of particle number eventually saturate as well (see below). The entanglement entropy for the pure state of the whole system is defined as the von Neumann entropy $S = -\text{tr} \rho_A \log \rho_A = -\text{tr} \rho_B \log \rho_B$ of the reduced density matrix of either subsystem. We always form the two bipartitions by dividing the system at the center bond.

The type of evolution considered here can be viewed as a “global quench” in the language of Calabrese and Cardy [12] as the initial state is the ground state of an artificial Hamiltonian with local fields. Evolution from an initial product state with zero entanglement can be studied efficiently via time-dependent matrix product state methods until a time where the entanglement becomes too large for a fixed matrix dimension. Since entangle-
ment cannot increase purely by local operations within each subsystem, its growth results only from propagation across the subsystem boundary, even though there is no conserved current of entanglement.

The first question we seek to answer is whether there is any qualitatively different behavior of physical quantities when a small interaction

\[ H_{\text{int}} = J_z \sum_i S_i^z S_{i+1}^z \]  

(2)
is added. With Heisenberg couplings between the spins \( J_z = J_{\perp} \), the model is believed to have a dynamical transition as a function of the dimensionless disorder strength \( \eta/J_z \). This transition is present in generic eigenstates of the system and hence exists at infinite temperature at some nonzero \( \eta \). The spin conductiv-

ity, or equivalently particle conductivity after the Jordan-

Wigner transformation, is zero in the many-body localized phase and nonzero for small enough \( \eta/J_z \). However, with exact diagonalization the system size is so limited that it has not been possible to estimate the location in the thermodynamic limit of the transition of eigenstates or conductivities.

We find that entanglement growth shows a qualitative change in behavior at infinitesimal \( J_z \). Instead of the expected behavior that a small interaction strength leads to a small delay in saturation and a small increase in final entanglement, we find that the increase of entanglement continues to times orders of magnitude larger than the initial localization time in the \( J_z = 0 \) case (Fig. 1). This slow growth of entanglement is consistent with prior observations for shorter times and larger interactions \( J_z = 0.5J_{\perp} \) and \( J_z = J_{\perp} \) [10, 11], although the saturation behavior was unclear. Note that observing a sudden effect of turning on interactions requires large systems, as a small change in the Hamiltonian applied to the same initial state will take a long time to affect the behavior significantly. We next explain briefly the methods enabling large systems to be studied.

To simulate the quench, we use the time evolving block decimation (TEBD) [13, 14] method which provides an efficient method to perform a time evolution of quantum states, \( |\psi(t)\rangle = U(t)|\psi(0)\rangle \), in one-dimensional systems. The TEBD algorithm can be seen as a descendant of the density matrix renormalization group [15] method and is based on a matrix product state (MPS) representation [16, 17] of the wavefunctions. We use a second-order Trotter decomposition of the short time propagator \( U(\Delta t) = \exp(-i\Delta t H) \) into a product of term which acts only on two nearest-neighbor sites (two-site gates). After each application, the dimension of the MPS increases. To avoid an uncontrolled growth of the matrix-dimensions, the MPS is truncated by keeping only the states which have the largest weight in a Schmidt decomposition.

In order to control the error, we check that the neglected weight after each step is small (\(< 10^{-6}\) ). Algorithms of this type are efficient because they exploit the fact that the ground-state wave functions are only slightly entangled which allows for an efficient truncation. Generally the entanglement grows linearly as a function of time which allows only the simulation of rather short times. In our case, however, the entanglement growth is logarithmic and thus it is possible to perform a time evolution over long time scales [11].

In order to study the asymptotic \((t \to \infty)\) behavior, we employ exact diagonalization techniques. We diagonalize the full Hamiltonian and construct \( U(t) \) which allows us to access very late times after the quench. Since the Hilbert space grows exponentially with the system size, we can only consider rather small systems. All the data in this paper are obtained by averaging over more than \( 10^4 \) field configurations \( \{h_i\} \) starting from a random product

![Figure 1](image-url)

**FIG. 1.** (a) Entanglement growth after a quench starting from a site factorized \( S_z \) eigenstate for different interaction strengths \( J_z \) (we consider a bipartition into two half chains of equal size). All data is for \( \eta = 5 \) and \( L = 10 \), except for \( J_z = 0.1 \) where \( L = 20 \) is shown for comparison. The inset shows the same data but with a rescaled time axis and subtracted \( J_z = 0 \) values. (b) Saturation values of the entanglement entropy as a function of \( L \) for different interaction strengths \( J_z \).
we have plotted the entanglement for both \( L = 10 \) and \( L = 20 \). While absolute value of the entanglement differs slightly, the two curves are indistinguishable after subtracting the non-interacting value (inset), suggesting that for the entanglement at the time scales explored, finite size effects are small.

In an infinite system, we expect the logarithmic growth of the entanglement to continue indefinitely. In a finite system, in contrast, it will saturate at late times at some value \( S_{\infty} \). The lower panel in Fig. 1 shows the system size dependence of this saturation value, as obtained by exact diagonalization. In the non-interacting case, this value is independent of system size as expected if the localization length \( \xi \ll L \). In the presence of interaction the saturation value is independent of the interaction strength (we have checked that the small difference between the curves at large \( L \) goes away as the saturation time is increased) and follows a volume law. For small sizes the result is roughly consistent with Ref. 10, although going to longer times we find that the saturation follows a volume law rather than being logarithmic in subsystem size as conjectured there. Such logarithmic dependence occurs at certain random-singlet quantum critical points in one dimension 13, but the present system is not critical by standard definitions.

The observation of a volume law for the saturation entanglement entropy suggests at first glance that the system may be partially thermalized, as a finite entanglement entropy per site is consistent with a thermal entropy. However, the saturation value of the entanglement entropy per site is much lower than the infinite-temperature thermal value associated with 2 states per site. Since, as shown below, particle number propagates much less than entanglement and may well be localized, the entanglement entropy at saturation may result from an incomplete thermalization where the system locally equilibrates among a restricted ensemble with particular values of particle number, energy, and other conserved quantities. This would be a many-body-localized version of the generalized Gibbs ensemble describing thermalization in some systems without disorder.

The time evolution of the half-chain particle number fluctuations, i.e., the variance of the total spin on half the chain, is plotted in the upper panel of Fig. 2. The behavior of the particle number fluctuations is qualitatively different than the entanglement entropy. Interactions do enhance the particle number fluctuations, but while there are signs of a logarithmic growth as for the entanglement, this growth slows down with time. The saturation values, similarly, are interaction dependent and only fractionally larger than in the non-interacting case. This does not seem to be a case of the system not having reached saturation, as increasing the saturation time by two orders of magnitude has a negligible effect on the saturation values. The half-chain energy variance behaves in a manner similar to the particle variance (data not shown). It

![Graph](image_url)
would therefore seem that particle transport is not fully ergodic, which would be consistent with a many-body localized phase.

Our results are consistent with a phase diagram consisting of a conventionally localized phase at zero interaction, a quasi-localized or many-body localized phase for moderate interactions, and a delocalized phase when interactions dominate disorder. Since all local measurements on a subsystem are entirely determined by the reduced density matrix of that subsystem, the entanglement entropy difference between Anderson and many-body localized phases will appear in any local measurement of entropy. Simple models can be constructed of a many-body localized phase with zero particle number and energy conductivities, but with infinite saturation entanglement, compared to finite saturation entanglement in the non-interacting case.

We comment briefly on the possibility that the particle and energy variances are not actually saturating but increase without limit, which cannot strictly be ruled out from our data. (This would still be consistent with zero conductivity if, for example, the continuing increase results from subdiffusive motion of particles.) It should be noted that the quantities studied here by matrix-product-state methods are not directly comparable to quantities previously studied by exact diagonalization, e.g., the level statistics of eigenstates or correlations in a single eigenstate. It is conceivable that there is a transition as a function of $\eta$ in such quantities but that the real-time evolution studied here is insensitive to that transition. However, if this is the case, it means that experiments must be carefully designed to detect the transition as the dynamics of a simple initial state are characterized better by glassy dynamics than ordinary localization.

If the ultimate dynamics on long time scales is dephased, as one part of the system interacts with a large region that can serve as a “bath”, then classical dynamics is appropriate, and in classical physics it has been known for many years that quenched random systems need not be diffusive, especially in 1D. One model leading to anomalous long-time dynamics was introduced by Sinai, who showed that one-dimensional Brownian motion is modified by the addition of a static Gaussian-correlated random force $F$,

$$\frac{dx}{dt} = \nu(t) + F(x). \quad (3)$$

The root-mean-squared displacement $R = \sqrt{\langle x^2 \rangle}$ of a particle from its initial location scales asymptotically as $R \sim \log^2 t$ rather than $R \sim \sqrt{t}$ as in ordinary diffusion. The scaling of $R$ can be obtained from a simple estimate of the time required to cross an occasional region of unfavorable potential. Another possibly relevant classical model follows from considering classical rate equations with a broad distribution of rates, which leads to logarithmic diffusion $R \sim \log t$ for intermediate times before ultimately crossing over to diffusion.

In conclusion, the many-body localized phase is fundamentally different in at least one measurable dynamical property, the creation of entanglement, from non-interacting Anderson localization. Two important questions for future work are a full characterization of other dynamical properties of this phase, including whether particles and energy are fully localized or propagate subdiffusively, and an understanding of how these properties connect to the unusual dynamical phase transition between the many-body localized phase and the delocalized phase.
