Abstract. The interfacial friction properties of GCL and geomembrane under different hydration conditions are discussed. In addition, the ionic solubility of hydration solution, the size of hydration normal stress and test conditions will affect the shear strength of GCL. In this paper, the friction properties of GCL upper geotextile and geomembrane interface are discussed from the following aspects: ① hydration solutions with different ionic concentrations (deionized water, 0.05mol/l CaCl$_2$ solution and 1:1 ethanol solution by volume); ② different types of hydration solutions (0.05mol/l CaCl$_2$ solution and 1:1 ethanol solution by volume); ③ different hydration normal stress conditions (pressureless hydration condition, 5kPa hydration condition and 10kPa hydration condition).

1 Research background

The shear failure of GCL generally occurs in the following three parts: inside the GCL; between the top surface and the overlying material; and between the bottom surface and the underlying material.[1] Among them, the latter two belong to the interface shear strength failure, and the former is more damaged in practical engineering. The research structure shows that the internal failure of GCL caused by reinforcement will not affect the slope environment. However, when the bentonite in GCL interlayer is hydrated, the shear strength of the system will decrease rapidly. This will lead to the relative sliding between the surface layer and the bottom layer of GCL.[2] If GCL is laid on the slope, not only the relative sliding between materials is easy to occur, but also the hidden sliding surface can easily appear due to the poor shear strength at this time. Considering that the bentonite in GCL may be extruded, the friction coefficient of other synthetic materials will also decrease. Therefore, the study on the interfacial shear strength between GCL and other geosynthetics has practical significance and engineering value for the application of GCL in landfill.[3]

2 Preparation of test specimens

The test materials include GCL, geomembrane and hydration solution. In the process of the experiment, GCL and geomembrane are the experimental objects of interface friction. In terms of hydration solution, the composition of landfill leachate is complex, including a variety of organic matter, inorganic matter and toxic and harmful components. With the exchange of ions, the concentration of pollutants in the filtrate has a strong fluctuation, whether in a short time or in a long term, and the process is extremely complex. In addition, the composition of leachate is also affected by the location and distribution of the area, different components of garbage and different landfill methods, and its composition also shows different changes.[4] Based on the laboratory test and the limitation of GCL material as sodium bentonite waterproof blanket, in order to analyse and compare the test results, the simulated leachate is deionized water, 0.05mol/l CaCl$_2$ solution and ethanol solution (the volume ratio of ethanol to water is 1:1). The reasons are as follows: ① Calcium ion and chloride ion are the main ions in landfill leachate. ② When landfill leachate interacts with sodium bentonite waterproof blanket, the ion exchange mainly shows that calcium ion replaces sodium ion. ③ Deionized water is selected for the test to provide a comparative basis for the shear strength analysis of GCL under the action of solution.[5]

3 Analysis of test results of interface friction between GCL and geomembrane under different hydration conditions

3.1 Analysis of test results of interface friction between hydrated GCL and geomembrane

It can be seen from Fig. 1 that under the same normal stress, the interfacial shear stress between GCL and geomembrane under pressureless hydration condition is larger than that between GCL and geomembrane under...
other conditions, the interfacial shear stress between GCL and geomembrane under 5kPa hydration condition is the second, and that between GCL and geomembrane under 10kPa hydration condition is the smallest. The interfacial shear stress of GCL is very close to that of geomembrane at 5kPa and 10kPa. The interface peak strength of GCL and geomembrane under pressureless hydration state is the largest, followed by 5kPa normal stress hydration state, and the minimum interface peak strength of GCL and geomembrane under 10kPa normal stress hydration state.

Table 1 shows that under the same normal stress, the peak value of interfacial shear stress of GCL under pressureless hydration condition is higher than that of GCL under 5kPa hydration condition and 10kPa hydration condition. The peak value of interfacial shear stress between GCL and geomembrane under pressureless hydration condition is 18.37% higher than that under 5kPa normal stress hydration condition and 8.05% higher than that under 10kPa normal stress hydration condition. It can be seen that the interfacial shear stress between GCL and geomembrane decreases with the increase of hydration normal stress.

Table 1. The improvement rate of GCL in different hydration conditions

| Normal stress | 50kPa | 100kPa | 150kPa | 200kPa |
|---------------|-------|--------|--------|--------|
| 5kPa Hydration conditions | 25.57% | 25.40% | 18.37% | 25.44% |
| 10kPa Hydration conditions | 11.29% | 13.19% | 8.05% | 16.64% |

Under the condition of pressureless hydration, the cohesion between GCL and geomembrane is the largest, followed by 5kPa normal stress hydration, and the lowest under 10kPa normal stress hydration condition; while under the three conditions, the number of internal friction angles of GCL and geomembrane interface friction under pressureless hydration is the largest, and the internal friction angle under 5kPa normal stress hydration is several times. The number of internal friction angle is the smallest under the condition of 10kPa normal stress hydration. In comparison, the interface shear strength between GCL and geomembrane under pressureless hydration is the largest, followed by 5kPa normal stress hydration, and the minimum under 10kPa normal stress hydration.

2.3 Analysis of GCL test results of 0.05mol/l CaCl₂ solution hydration

It can be seen from Figure 3 that under the same normal stress, the interface stress curve between GCL and geomembrane under pressureless hydration state is higher than that under other conditions, the interfacial shear stress value between GCL and geomembrane under 5kPa hydration condition is the second, and that between GCL and geomembrane under 10kPa hydration condition is the smallest. The interfacial shear stress of GCL is very close to that of geomembrane at 5kPa and 10KPa. The interface peak strength between GCL and geomembrane is > 5kPa normal stress hydration state > 10 kPa normal stress hydration state under pressureless hydration state.

It is shown in Table 3 that under the same normal stress, the peak value of interfacial shear stress under pressureless hydration condition of GCL is higher than that of GCL under 5kPa hydration condition and 10kPa hydration condition. The peak value of interfacial shear stress between GCL and geomembrane under pressureless hydration is 0.84% higher than that under 5kPa normal stress hydration condition, and 14.96% higher than that under 10kPa normal stress hydration condition. It can be seen that the interfacial shear stress between GCL and geomembrane after hydration with 0.05mol/l CaCl₂ solution decreases with the increase of hydration normal stress.
Under the condition of pressureless hydration, the cohesion between GCL and geomembrane is the largest, followed by 5kPa normal stress hydration, and the lowest under 10kPa normal stress hydration; and under the three conditions, the number of internal friction angles of GCL and geomembrane under the condition of pressureless hydration is the largest, the internal friction angle of 5kPa normal stress hydration is several times, and that of 10kPa normal stress hydration is the highest. The number of internal friction angles is the smallest. In comparison, the interface shear strength between GCL and geomembrane under pressureless hydration is the largest, followed by 5kPa normal stress hydration, and the minimum under 10kPa normal stress hydration.

3.3 Analysis of hydration test results of ethanol (volume ratio 1:1)

It can be seen from Fig. 5 that under the same normal stress, the interface shear stress curve between GCL and geomembrane under pressureless hydration state and between GCL and geomembrane under 5kPa hydration condition are higher than that between GCL and geomembrane under 10kPa hydration condition. The interfacial shear stress curves of GCL and geomembrane under pressureless hydration state and GCL with geomembrane under 5kPa hydration condition are intertwined together, without obvious regularity. However, it can be seen from the figure that the interface peak strength between GCL and geomembrane is the largest under 5kPa hydration condition, followed by GCL and geomembrane under pressureless hydration condition, and the minimum interface peak strength between GCL and geomembrane under 10kPa normal stress.

| GCL and geomembrane | c/kPa | φ (°) |
|---------------------|-------|-------|
| No pressure Hydration conditions | 9.44 | 4.18° |
| 5kPa Hydration conditions | 9.33 | 3.94° |
| 10kPa Hydration conditions | 7.445 | 3.72° |

It is shown in Table 5 that under the same normal stress, the peak value of interfacial shear stress under pressureless hydration condition of GCL is higher than that of GCL under 5 kPa hydration condition and 10 kPa hydration condition. The peak shear stress ratio of GCL to clay under pressureless hydration condition is 3.24% less than that under 5kPa normal stress hydration condition, and is at least 8.04% higher than that under 10 kPa normal stress hydration condition. It can be seen that the interfacial shear stress between GCL and clay decreases with the increase of hydration normal stress.
Table 5. The improvement rate of GCL in different hydration conditions

| Normal stress | 50kPa | 100kPa | 150kPa | 200kPa |
|---------------|-------|--------|--------|--------|
| 5kPa Hydration conditions | -3.24% | 10.90% | 10.22% | 0.45%  |
| 10kPa Hydration conditions | 8.04% | 8.04% | 19.78% | 10.04% |

Under the condition of pressureless hydration, the cohesion between GCL and geomembrane is the largest followed by 5kPa normal stress hydration and 10kPa normal stress hydration. Under the three conditions, the number of internal friction angles of GCL and geomembrane interface under pressureless hydration is the largest, the internal friction angle under 5kPa normal stress hydration is several times, and the internal friction angle number under 10kPa normal stress hydration condition is the minimum. In comparison, the interface shear strength between GCL and geomembrane under pressureless hydration is the largest, followed by 5 kPa normal stress hydration, and the minimum under 10 kPa normal stress hydration.

Fig. 6. GCL and geomembrane maximum shear stress and normal stress (τ - p) relationship graph

Table 6. Test results of interface friction between different hydration solutions GCL and geomembrane

| Geotechnical materials | Hydration solution | Cohesion (c/kPa) | Friction angle (°) |
|------------------------|--------------------|------------------|-------------------|
| GCL and geomembrane    | No pressure        | 10.33            | 4.12              |
|                        | Hydration conditions |                 |                   |
|                        | 5kPa               | 9.954            | 3.89              |
|                        | 10kPa              | 8.94             | 3.60              |

4 Summary

The conclusions obtained through the above-mentioned experimental analysis are as follows:

1. The shear strength of GCL and clay is the largest under pressureless hydration condition; the interfacial shear stress between GCL and geomembrane decreases with the increase of hydration normal stress after deionized hydration, and the maximum shear strength of GCL and geomembrane under pressureless hydration is 5kPa; the shear strength under normal stress hydration is the second, and the shear strength under 10kPa normal stress hydration is the lowest.
2. The interface shear strength between GCL and geomembrane is the largest under pressureless hydration, followed by 5kPa normal stress hydration, and the lowest under 10kPa normal stress hydration.
3. The shear strength of GCL and geomembrane under pressureless hydration is the largest, followed by 5kPa normal stress hydration, and the lowest under 10kPa normal stress hydration.
4. Under the condition of pressureless hydration, 5kPa normal stress hydration and 10kPa normal stress hydration, the shear resistance of interface friction between GCL and geomembrane is ethanol > 0.05mol/L CaCl₂ solution > deionized water.
