Aggregation of initially stably structured proteins is involved in more than 20 human amyloid diseases. Despite intense research, however, how this class of proteins assembles into amyloid fibrils remains poorly understood, principally because of the complex effects of amino acid substitutions on protein stability, solubility, and aggregation propensity. We address this question using β₂-microglobulin (β2m) as a model system, focusing on D76N-β2m that is involved in hereditary amyloidosis. This amino acid substitution causes the aggregation-resistant wild-type protein to become highly aggregation prone in vitro, although the mechanism by which this occurs remains elusive. Here, we identify the residues key to protecting β2m from aggregation by coupling aggregation with antibiotic resistance in E. coli using a tripartite β-lactamase assay (TPBLA). By performing saturation mutagenesis at three different sites (D53X-, D76X-, and D98X-β2m) we show that residue 76 has a unique ability to drive β2m aggregation in vivo and in vitro. Using a randomly mutated D76N-β2m variant library, we show that all of the mutations found to improve protein behavior involve residues in a single aggregation-prone region (APR) (residues 60 to 66). Surprisingly, no correlation was found between protein stability and protein aggregation rate or yield, with several mutations in the APR decreasing aggregation without affecting stability. Together, the results demonstrate the power of the TPBLA to develop proteins that are resilient to aggregation and suggest a model for D76N-β2m aggregation involving the formation of long-range couplings between the APR and Asn76 in a nonnative state.

**Significance**

Protein aggregation is a major problem for human health. However, our understanding of how folded proteins aggregate into amyloid lags behind. Using the tripartite β-lactamase assay (TPBLA) with our test protein, β2m, we show the ability to differentiate the behavior of single-point variants and highlight the remarkable sensitivity to the identity of the residue at position 76. After evolving the aggregation-prone protein, D76N-β2m, the only mutations able to improve D76N-β2m behavior in vivo involve residues in a single 7-residue sequence of the protein. Further characterization in vitro shows that a single-point mutant in this region can abolish D76N-β2m aggregation.

5 and 15 residues long) can be achieved with confidence using these algorithms (25, 26). However, when an APR is contained within a long IDP or is embedded within a globular protein, it remains challenging to predict whether a particular protein sequence will assemble into amyloid, since aggregation depends on each of these criteria (and others) (3).

Recent developments in experimental methods using evolution and selection approaches have the potential to provide large datasets of protein sequences with different behavior in vitro or in a cellular setting (3). We have previously reported one such approach, the tripartite β-lactamase assay (TPBLA) (27, 28)—which has been used to enhance the thermodynamic stability of globular proteins (29, 30)—to rank the aggregation propensity of variants of Aβ and IAPP (28), to screen for small-molecule inhibitors of aggregation (28), and to evolve aggregation-resistant proteins of relevance to biopharma (27).

In the TPBLA, a peptide or protein of interest is fused in-frame between the two domains of TEM-1 (Temoneira-1) β-lactamase (β-lac), and the fusion protein is expressed in the periplasm of E. coli (Fig. 1A). Antibiotic resistance of the resulting bacteria (Fig. 1B), measured by an in vivo growth score in the presence of different concentrations of ampicillin, is then used to reflect the inherent characteristic (stability/solubility/ aggregation propensity or other) of the inserted sequence since a paucity in any such characteristic will reduce the concentration of folded β-lac in the periplasm and, hence, the ability of the bacteria to grow in the presence of an antibiotic. The TPBLA is tolerant of the insertion of peptides, as well as longer IDPs and structured protein domains (single- and two-domain proteins up to 40 kDa in size have been successfully analyzed to date) (27, 28, 30). It also has the advantage that the periplasm is oxidatively tolerant of the insertion of peptides, as well as longer IDPs and IDPs that contain disulphide bonds. In the case of short peptides and IDPs, the TPBLA yields a relatively simple readout since the overriding feature dominating selection is the inherent aggregation propensity of the sequence (28). In the case of stably folded proteins, the TPBLA provides a readout that correlates with protein solubility and stability (27). For proteins that are folded but aggregation prone, such as the folded precursors of amyloid disease, the readout is potentially complex, as many parameters can influence the in vivo growth score, including inter alia protein stability, aggregation propensity, solubility, and other characteristics.

Here, we report the use of the TPBLA to explore the role of the protein sequence in determining the aggregation of the naturally amyloidogenic protein, β2m. β2m is 99 residues in length (10.8 kDa) and has a seven-stranded β-sandwich immunoglobulin fold that is stabilized by a single disulphide bond linking Cys25 and Cys80 (31, 32) (Fig. 2A). The protein forms the noncovalently bound light chain of the major histocompatibility complex class 1 (MHC 1) (33) and is important for antigen presentation (34, 35). In healthy individuals, β2m dissociates from the MHC 1 as part of its catabolic cycle, whereupon it is cleared from the serum via the kidneys (11). However, in individuals with renal failure, β2m is no longer efficiently removed from the blood, resulting in an increased serum β2m concentration and the formation of amyloid fibrils that deposit in the joints in the disorder known as DRA (11–13).

In 2012, the first familial β2m variant involved in hereditary amyloid disease was identified (15). The amyloid deposits were found in the visceral organs and contained the variant D76N-β2m, despite the individuals being heterozygous for the mutation and having normal serum β2m levels (15). Subsequent analysis revealed that D76N-β2m is less stable than WT-β2m, but why the substitution of Asp to Asn in a solvent-exposed loop enhances the amyloid propensity of the protein remains mysterious since other amino acid substitutions that reduce stability to a similar, or an even greater, extent (e.g., V37A-β2m) have no effect on protein aggregation (36). Substitution of each of the other six Asn residues in the β2m sequence to Asp does not induce amyloid formation, highlighting a unique role of residue 76 in controlling aggregation of the protein (37). While aggregation of WT-β2m is driven by the formation of a partially folded state containing a nonnative trans Pro32 (known as the I1-state) (38), the population of the I1-state is not enhanced for the more rapidly aggregating D76N-β2m, suggesting that WT- and D76N-β2m aggregate through distinct mechanisms (31). Indeed, it has been hypothesized that a different species, possibly a native-like state (named the N+ -state), could be responsible for D76N-β2m aggregation (39), highlighting the complex relationship of protein sequence and aggregation mechanism for this protein.

To explore the relationship between sequence and amyloid propensity for D76N-β2m in more detail, we here combined in vivo, in vitro, and in silico methods to search for amino acid substitutions that reduce the aggregation propensity of the protein. Using saturation mutagenesis of residue 76 analyzed by the TPBLA alongside analysis of saturation libraries of two other solvent-exposed Asp residues (D53 and D98) and in vitro determination of the structural properties, stability, and aggregation...
rate of the D76X variants, we show a remarkable specificity of the identity of residue 76 in determining β2m aggregation in vitro and in vivo that could not be recapitulated by in silico prediction methods. Random mutagenesis and selection for enhanced antibi-
totic resistance using the TPBLA was then used to screen for amino acid substitutions able to reduce D76N-

\[ β_2m \]

aggregation. The results revealed a single region of the β2m sequence, involving residues 60 to 66, that is required for D76N-

\[ β_2m \]

aggregation. This region has a high predicted and experimentally validated aggregation propensity and has been shown previously to control the rate of aggregation of acid unfolded WT-

\[ β_2m \]

into amyloid by tailoring its conformational dynamics (40). The results are consistent with a model for D76N-β2m in which the substitution of Asp76 with Asn destabilizes the native protein and increases the population of nonnative conformers that have an enhanced aggregation propensity, in contrast with WT-β2m and its truncation variant ΔN6 that aggregate via their \[ \Gamma_1 \] -states (41). The results highlight the power of protein evolution and selection methods to generate proteins able to resist aggregation that cannot be predicted using current algorithms. Such data could be used in the future to inform in silico methods better able to predict aggregation of amyloidogenic proteins.

Results

Experimental and Predicted Differences in Stability and Aggregation of WT- and D76N-β2m. As previously described (15), WT- and D76N-β2m have similar structures (root-mean-
square deviation [RMSD] of 0.33 Å over all heavy atoms) (Fig. 2B) but profoundly different abilities to aggregate into amyloid fibrils in vitro (the half time of aggregation \( T_{1/2} \) for D76N-β2m is 13.7 \( \pm \) 1.6 h, while WT-β2m does not aggregate...

Saturation Mutagenesis at Positions 53, 76, and 98 Measured Using the TPBLA. To confirm the ability of the TPBLA to detect changes in β-m aggregation, the assay was performed on WT- and D76N-β-m by inserting these sequences individually into the linker of β-lac. Each variant exhibited dramatically different scores in the TPBLA (Fig. 1C), with D76N-β-m giving a significantly lower score compared to WT-β-m (enumerated as the area under the MCDgrowth curve [AUC] of 680 ± 10 AUC and 191 ± 31 AUC for WT- and D76N-β-m, respectively), consistent with previous results (28) (Fig. 1D). These data highlight the sensitivity of the TPBLA to detect the effect of single-point amino acid substitutions on β-m behavior.

Next, each of the 20 natural amino acids was placed at position 76 in the protein sequence using mutagenesis, and the in vivo growth score of bacteria expressing each of these variants was measured over a range of ampicillin concentrations (0 to 140 μg ml⁻¹) (SI Appendix, Fig. S1A). The results (Fig. 3A) were striking, showing that D76-β-m (corresponding to WT-β-m) has by far the highest score (~700 AUC), consistent with this protein being highly resilient to aggregation and/or degradation in the E. coli periplasm. A second group of residues, with a significantly reduced score compared to Asp76, includes the D76E- and D76A-β-m variants (~400 AUC [P = 0.01 compared with WT-β-m]), while a third group contains the remaining 17 D76X-β-m variants, which have significantly decreased scores (P = 0.003 compared with D76E/Asp-β-m) (Fig. 3A). This last group of variants has gradually decreasing scores (ranging from ~300 [for D76I-β-m] to ~50 AUC [for D76R-β-m]). Notably, the substitution D76N lies in the middle of this third group, but its score is not significantly different from those of other variants in this group. Overall, the results show that the presence of a negatively charged Asp protects β-m from aggregation, at least as judged by the TPBLA, with the negatively charged D76E-β-m or neutral D76A-β-m providing some, albeit more limited, protection as judged by this assay.

To better understand the importance of substitutions at residue 76 on the behavior of β-m, two additional Asps were selected for analysis by the TPBLA: Asp53 (a solvent-exposed residue in the center of the edge D-strand of the β-sandwich fold) and Asp98 (also solvent exposed and the penultimate residue of the protein) (Fig. 2A). Comparison of the MCDgrowth curves of D76N-, D53N-, and D98N-β-m showed that each has a significantly different score compared to WT-β-m (SI Appendix, Fig. S1–C), with D98N-β-m having the highest score (~600 AUC), followed by D53N-β-m (~500 AUC), and D76N-β-m with the lowest score (~200 AUC) (P < 0.04 for the three variants compared with WT-β-m; SI Appendix, Figs. S2A). This indicates that an Asp-to-Asn substitution at these sites affects β-m differently, depending on the residue’s position in the native structure. Since these variants all involve an Asp-to-Asn substitution at a solvent-exposed site, the difference in MCDgrowth of these variants cannot be attributed to differences in overall protein charge or solubility. Accordingly, no significant difference in protein solubility or aggregation propensity was predicted for these three variants using the algorithms Tango (18), CamSol (16), or Aggrescan 3D (23, 24) (SI Appendix, Figs. S2B and S3 D–F).

Saturation mutagenesis was next carried out at positions 53 and 98, and the MCDgrowth of the resulting 40 variants was determined using the TPBLA (SI Appendix, Fig. S1 B and C). By contrast with amino acid substitutions at position 76, which result in proteins that are sensitive to the identity of the amino acid at that site, residue 98 is resilient to substitution, with little change in the in vivo growth score for 19 of the 20 sequences (the sole exception is D98C, which could be explained by the formation of an incorrect intra- or intermolecular disulfide bond) (SI Appendix, Fig. S1C). Notably, Cys substitution at residues 53 and 76 also results in a reduced in vivo growth score (Fig. 3A and B). Interestingly, the D53X-β-m series resulted in proteins with a behavior in the TPBLA distinct to those of the resilient D98X-β-m or sensitive D76X-β-m series, with a gradual change in the in vivo growth score across all 20 residue types (SI Appendix, Fig. S1B). Consistent with this, a poor correlation is observed between the in vivo growth scores of D98X-β-m and D53X/D76X-β-m, as judged by their rank-based Spearman correlations of 28 and 43%, respectively (SI Appendix, Fig. S3).

Whether a protein aggregates depends on the balance of many factors—including protein structure, stability, solubility, and inherent aggregation propensity—and can be modulated by the sequence (such as the inclusion of charges or gatekeeper residues local to an APR; ref. 45). The predicted properties of the 20 sequence variants at positions 76, 53, and 98 were determined using the algorithms Tango (18), CamSol (16), and Aggrescan 3D (23, 24) and compared with the in vivo growth scores of the variants at each position. For D76X-β-m, a perfect correlation (r = 100% using a rank-based Spearman correlation; SI Appendix, Fig. S4) was observed between protein solubility and in vivo growth score, while Tango (18) and Aggrescan3D (23, 24) did not correlate (Fig. 3D). For D98X-β-m, the in vivo growth score and the predictions of all three algorithms were not significantly affected by substitution, suggesting that the identity of this residue plays little or no role in determining aggregation in vivo or in silico (Fig. 3F). For D53X-β-m, where the substitution site is at an edge-strand, a different scenario ensues. For this series of variants, protein
behavior can be divided roughly into four groups, depending on amino acid type (with a statistically significant difference between each group: \( P < 0.05 \); Fig. 3B). The first group contains WT- and D53E-\( \beta_m \), indicating that increasing the size of the acidic sidechain does not affect the protein’s behavior. The second group contains mostly positively charged or polar residues (D53Q-, D53K-, D53T-, D53S-, D53R-, and D53F-\( \beta_m \)), as well as D53A-, D53P-, and D53G-\( \beta_m \). The third group contains the remaining hydrophobic residues (D53V-, D53L-, D53H-, D53M-, D53Y-, D53W-, and D53F-\( \beta_m \)), while the fourth group contains only D53C-\( \beta_m \). Aggrescan3D (23, 24) and CamSol (16) were able to capture the rank order and in vivo growth scores of the D53X-\( \beta_m \) variants, with Tango performing less well (Fig. 3E and SI Appendix, Fig. S5). Interestingly, an inverse correlation was observed between \( \beta \)-strand propensity and the rank order of the in vivo growth score (\( r = 75\% \) using a rank-based Spearman correlation) for the variants at residue 53 (i.e., residues with a higher \( \beta \)-strand propensity resulted in a lower in vivo growth score; SI Appendix, Fig. S5 E and F). This observation could be rationalized by the known selection against structures with edge \( \beta \)-strands that are solvent exposed and straight, presumably as a protective mechanism against in vivo aggregation (SI Appendix, Fig. S5) (46). Overall, the results portray the sensitivity of the TPBLA to single amino acid substitutions in a protein sequence and reveal the different responses to substitutions at the three different sites in \( \beta_m \) analyzed here.

Stability and Aggregation of Purified Proteins Mutated at Position 76. To better understand the effect of the amino acid substitutions at residue 76 on structure, stability, and aggregation potential, the 20 D76X-\( \beta_m \) variants were cloned (in the absence of \( \beta \)-lac), expressed in \( E. coli \), and purified (SI Appendix, Materials and Methods). The yields of pure protein varied markedly, from 40 mg pure protein/L of culture for WT-\( \beta_m \) (Asp76) to 0.4 mg pure protein/L of culture for D76L-\( \beta_m \) (SI Appendix, Table S3). The apparent thermal stability (\( T_{m \text{app}} \)) of each protein measured by far-UV CD (far-ultra-violet circular dichroism) also varied markedly, from 65.2 ± 0.4 °C for WT-\( \beta_m \) to 37.9 ± 0.8 °C for D76R-\( \beta_m \) (Fig. 4A; see also SI Appendix, Fig. S6 and Table S3). This variation is surprising, given that the sidechain of residue 76 is solvent exposed and makes just three hydrogen bonds (to the sidechains of N42, T73, and Y78) in the crystal structure of WT- and D76N-\( \beta_m \) (SI Appendix, Fig. S7 A and B). Nonetheless, a clear correlation (\( r = 86\% \) using rank-based Spearman correlation; SI Appendix, Fig. S8 A and B) is observed between \( T_{m \text{app}} \) and the in vivo growth score, suggesting that stability (as well as solubility) is an important parameter in determining the readout of the TPBLA for this series of variants (Fig. 3D).
Finally, the aggregation rate of each variant was determined (monitored by thioflavin T [ThT] fluorescence) \( (SI \text{ Appendix, Fig. S6}) \). Here, again, a wide variation in behavior was observed. As expected, WT-\( \beta \text{-m} \) did not form detectable amyloid fibrils under the conditions employed (40 \( \mu \text{M} \) protein, 25 mM sodium phosphate buffer, 115 mM NaCl, pH 6.2, 37 °C, and shaking), while D76N-\( \beta \text{-m} \) formed amyloid-like fibrils the most rapidly of all 20 variants under the conditions employed (\( T_{\text{half}} \) 9.6 ± 3.8 h) \( (SI \text{ Appendix, Table S3}) \). Of the remaining variants, nine (D76A-, D76T-, D76S-, D76V-, D76Q-, the sole exception of D76M-\( \beta \text{-m} \)) \( (SI \text{ Appendix, Table S3}) \) failed to aggregate in vitro under the conditions employed. D76N-, D76Q-, and D76M-\( \beta \text{-m} \), which have intermediate in vivo growth scores, aggregate the most rapidly (\( T_{\text{half}} \) 60 to 70 h for D76E- and D76P-\( \beta \text{-m} \); Fig. 4B and \( SI \text{ Appendix, Table S3}) \). Indeed, there is only a poor correlation between the in vivo growth score and the \( T_{\text{half}} \) value \( (r = 28\% \) using rank-based Spearman correlation; \( SI \text{ Appendix, Fig. 3C and D}) \), with the four variants with the lowest in vivo growth score (worst behavior; D76W-, D76F-, D76C-, and D76R-\( \beta \text{-m} \)) failing to aggregate in vitro under the conditions employed. D76N-, D76Q-, and D76M-\( \beta \text{-m} \), which share an amide sidechain at residue 76. For D76N-\( \beta \text{-m} \), the network of hydrogen bonds involving the sidechains of N42, T73, and Y78 found in the CD and EF loops of WT-\( \beta \text{-m} \) is maintained in the variant (\( SI \text{ Appendix, Fig. S7 A and B}) \). By contrast, the sidechain of Gln76 moves away from Asn42 in the variant D76Q-\( \beta \text{-m} \); instead, Gln76 hydrogen bonds with Lys41 (\( SI \text{ Appendix, Fig. S7 E and F}) \), similar to D76E-\( \beta \text{-m} \) (\( SI \text{ Appendix, Fig. S7 B}) \). For other variants, the loop structure is maintained despite these hydrogen bonds either not forming (D76A-, D76G-, and D76Y-\( \beta \text{-m} \); \( SI \text{ Appendix, Fig. S7 C, G, and H}) \), or being reduced in number (D76K-\( \beta \text{-m} \)); N42, and D76S-\( \beta \text{-m} \) hydrogen bonds to N42 and T73; \( SI \text{ Appendix, Fig. S7 I and D}) \). Together, these observations indicate that the sidechain chemistry at residue 76 plays a role in protein stability and aggregation, but the behavior of the variants cannot be rationalized by their crystal structures alone.

\[ \text{Fig. 4. Stability, aggregation, and crystal structures of the D76X-\( \beta \text{-m} \) variants. (A) Protein stability represented by } T_{\text{m,app}} \text{ was determined for the 20 D76X-\( \beta \text{-m} \) variants using temperature ramp monitored by far-UV CD at 216 nm } (SI \text{ Appendix, Materials and Methods}) \text{ The error bars represent the fitting error. The dashed line at 60 °C identifies proteins (WT-\( \beta \text{-m} \)) whose high } T_{\text{m,app}} \text{ prevents aggregation, while the line at 48 °C indicates the } T_{\text{m,app}} \text{ below which the D76X-\( \beta \text{-m} \) variants fail to aggregate over the course of these experiments or do slow very slowly (note: D76E-\( \beta \text{-m} \) has a thermal stability slightly above 48 °C). (B) Protein aggregation rate represented by } T_{\text{half}} \text{ calculated for all D76X-\( \beta \text{-m} \) variants using ThT fluorescence measurements. The error bars represent one SD of the mean from 8 to 10 technical repeats (two biological replicates were performed, but only one is shown here). The dotted lines separate the stable versus unstable variants in A and the aggregation-prone and aggregation-resilient variants in B. Each amino acid type is colored the same in A and B, and the variants are ordered identically to Fig. 3A (i.e., high to low in vivo growth score). ‘D’ corresponds to WT-\( \beta \text{-m} \). The asterisk in B corresponds to variants that started to aggregate just before the endpoint (100 h). (C) Superposition of the crystal structures of nine \( \beta \text{-m} \) variants: WT- (PDB 1LDS; ref. 61), D76A- (PDB 7NMO), D76E- (PDB 7NN5), D76G- (PDB 7NMT), D76K- (PDB 7NN5), and D76Y-\( \beta \text{-m} \) (PDB 7NMY) showing that the amino acid substitutions at residue 76 do not alter the structure of the proteins significantly, including the EF loop that contains residue 76.\]
Evolving D76N-β_{2m} to Reduce Its Aggregation Propensity.

Having established that the TPBLA can be used to differentiate the effects of amino acid substitutions at positions 53, 76, and 98 in β_{2m}, we next sought to use the assay as a screen for directed evolution to select for D76N-β_{2m} variants with improved properties, selected by an increased in vivo growth score. Genetic variation was introduced into the gene encoding D76N-β_{2m} using error-prone PCR before inserting the resulting library (βLa-D76N-β_{2m}*) into the β-lac vector (SI Appendix, Materials and Methods). The DNA sequences of 22 clones in the naïve library revealed an average mutational frequency of 10.9 base pair (b.p.) mutations per 1,000 b.p. (corresponding to 3.2 b.p. mutations per D76N-β_{2m} gene, equivalent to 2.4 amino acid substitutions per protein sequence). To screen for variants with enhanced properties, the βLa-D76N-β_{2m} plasmid library was transformed into E. coli SCS1 cells, and the bacteria were plated onto agar containing 120 or 140 μg mL^{-1} of ampicillin. In total, 1,000 and 100 colonies, respectively, were observed after transformation with βLa-D76N-β_{2m}*. Transformation with the undiversified βLa-D76N-β_{2m} plasmid yielded five and zero colonies at 120 or 140 μg mL^{-1} of ampicillin, respectively, suggesting that some mutations in βLa-D76N-β_{2m} increase the expression of functional βLa-β_{2m}. DNA sequencing of 209 colonies selected randomly at these two antibiotic concentrations yielded 56 unique sequences involving amino acid substitutions at 52 different sites that are scattered throughout the protein sequence, including residues in the β-strands and their connecting loops (SI Appendix, Fig. S9A). Ten of these unique sequences result in an amino acid substitution at residue 76, of which nine contain the WT’ reversion substitution (N76D), either in isolation or in combination with either one or two additional amino acid changes, while one contained the substitution N76S in combination with other substitutions in the APR or elsewhere, or combination with either an amino acid substitution at residues 60 or 65, respectively) each improved the in vivo growth score compared with D76N-β_{2m} (Fig. 5B). While L64D only slightly (but significantly) improves the in vivo growth score of D76N-β_{2m}, the substitution L65K improves the score dramatically, such that this variant behaves similarly to WT-β_{2m}. Notably, no correlation is observed between the in vivo growth score and the predictors Tango (18), Solubis (21, 22) was used to design two single-residue substitutions in the APR that are each predicted to significantly reduce the aggregation propensity of D76N-β_{2m} (L64D ΔTango −750.9 and L65K ΔTango −560.0). These substitutions are also predicted to destabilize the protein (ΔΔG° = 4.70 and 1.17 kcal mol^{-1} for L64D and L65K, respectively, calculated using FoldX; ref. 17). As predicted, the introduction of a negatively charged (Asp) or positively charged (Lys) residue into the center of the APR (at residue 64 or 65, respectively) each improved the in vivo growth score of D76N-β_{2m} (colored orange in Fig. 5B). While L64D only slightly (but significantly) improves the in vivo growth score of D76N-β_{2m}, the substitution L65K improves the score dramatically, such that this variant behaves similarly to WT-β_{2m}. Notably, no correlation is observed between the in vivo growth score and the predictors Tango (18), CamSol (16), or Aggrescan 3D (23, 24) (∂ < 25% using rank-based Spearman correlation; SI Appendix, Fig. S11), consistent with the complexity in factors that determines the behavior of D76N-β_{2m} variant in the TPBLA.

The APR of β_{2m}, ^{60}WSFYLLY^{66}, is composed mainly of aromatic and hydrophobic residues, consistent with its high predicted Tango score (18) (Fig. 2H) and measured aggregation propensity (as an isolated peptide; ref. 48). All amino acid substitutions resulting from the error-prone PCR decrease the hydrophobicity of the APR by substitution with a polar or charged residue (Lys, His, Arg, Asp, Ser, Asn, or Gln), by reducing the size of the sidechain (e.g., Phe to Leu or Gly), or by incorporation of the β-strand breaking residue Pro. Consistent with this, analysis of the D76N_F22L- and D76N_K48E-β_{2m} variants individually using the TPBLA yielded proteins with slightly reduced in vivo growth scores compared with D76N-β_{2m}, indicating that individual alteration of these three residues has no beneficial effect on D76N-β_{2m} (SI Appendix, Fig. S9B). We, thus, define the APR of D76N-β_{2m} as spanning residues 60 to 66 (^{60}WSFYLLY^{66}).

In all, 13 different amino acid substitutions in the APR (residues 60 to 66, ^{60}WSFYLLY^{66}) were found either singly, in combination with other substitutions in the APR or elsewhere, or both (SI Appendix, Table S7). These 13 single variants were cloned into βLa-D76N-β_{2m}, and their in vivo growth scores were determined using the TPBLA. All increased the in vivo growth score of D76N-β_{2m} (colored green for residues 60 to 66 in Fig. 5B), with two substitutions (W60G and Y63D) giving scores higher than WT-β_{2m} (Fig. 5B). This highlights a key role of the APR in defining the properties of D76N-β_{2m} in the TPBLA. Notably, the best-scoring substitution of all evolved variants was W60G (Fig. 5B). This solvent-exposed tryptophan lies in the DE loop of native β_{2m} and is required for its function (49). Substitution with glycine has been shown to stabilize the native protein and to reduce its aggregation propensity (49, 50). Instead of glycine, arginine was found in four of the nine variants substituted for W60. This accords with previous work showing that either W60R or W60C also reduces aggregation propensity (39, 51).

To confirm the importance of residues 60 to 66 in determining the behavior of D76N-β_{2m} in the TPBLA, Solubis (21, 22) was used to design two single-residue substitutions in the APR that are each predicted to significantly reduce the aggregation propensity of D76N-β_{2m} (L64D ΔTango −750.9 and L65K ΔTango −560.0). These substitutions are also predicted to destabilize the protein (ΔΔG° = 4.70 and 1.17 kcal mol^{-1} for L64D and L65K, respectively, calculated using FoldX; ref. 17). As predicted, the introduction of a negatively charged (Asp) or positively charged (Lys) residue into the center of the APR (at residue 64 or 65, respectively) each improved the in vivo growth score of D76N-β_{2m} (colored orange in Fig. 5B). While L64D only slightly (but significantly) improves the in vivo growth score of D76N-β_{2m}, the substitution L65K improves the score dramatically, such that this variant behaves similarly to WT-β_{2m}. Notably, no correlation is observed between the in vivo growth score and the predictors Tango (18), CamSol (16), or Aggrescan 3D (23, 24) (∂ < 25% using rank-based Spearman correlation; SI Appendix, Fig. S11), consistent with the complexity in factors that determines the behavior of D76N-β_{2m} variant in the TPBLA.

The APR of β_{2m}, ^{60}WSFYLLY^{66}, is composed mainly of aromatic and hydrophobic residues, consistent with its high predicted Tango score (18) (Fig. 2H) and measured aggregation propensity (as an isolated peptide; ref. 48). All amino acid substitutions resulting from the error-prone PCR decrease the hydrophobicity of the APR by substitution with a polar or charged residue (Lys, His, Arg, Asp, Ser, Asn, or Gln), by reducing the size of the sidechain (e.g., Phe to Leu or Gly), or by incorporation of the β-strand breaking residue Pro. Consistent with this, analysis of the 46 unique sequences using Solubis (21, 22) predicts that 45 of the 46 variants have reduced aggregation propensity compared to WT- and D76N-β_{2m} (the sole exception is D76N_F62L-H84R-W95R-β_{2m} (clone 27), which is the only substitution in the APR that maintains a hydrophobic residue [other than substitution with Pro]; SI Appendix, Fig. S10A). Most of these variants (44 of the 46 unique sequences) have a concomitant predicted decrease in stability (ΔΔG° > 1 kcal mol^{-1}; SI Appendix, Fig.
S10A4 (with the exception of D76N_W60R-β2m [clone 9] and D76N_S57G-W60R-β2m [clone 11], which only slightly decrease the predicted aggregation propensity; ΔTango = −130), consistent with previous results suggesting that reducing aggregation by sequence alteration generally comes at the cost of reducing protein stability (S2).

Finally, to explore whether amino acid substitutions at residues outside of the APR could decrease aggregation—even though they were not observed here experimentally—saturation mutagenesis of every residue in D76N-β2m was performed in silico using Solubis (21, 22) (SI Appendix, Fig. S12). Consistent with the single dominant APR in the β2m sequence, these results showed that of the 1,900 possible amino acid substitutions, the only substitutions that decrease aggregation (53 single-point variants for which ΔTango > −200; SI Appendix, Fig. S12) involve residues in the APR (with the sole exception of Y67P, ΔTango = −303). Of these 53 single-point variants, 89% are predicted to be destabilized (ΔΔG° > 1 kcal mol⁻¹) relative to D76N-β2m, while only six variants (11%) either have no effect on stability (D76N_L65E-, D76N_L65R-, D76N_Y63K-, D76N_W60E-, and D76N_S61D-β2m; ΔΔG° < 1 kcal mol⁻¹) or marginally stabilize D76N-β2m (D76N_S61E-β2m; ΔΔG° = −0.85 kcal mol⁻¹) (SI Appendix, Fig. S12).

**Purified Proteins with Sequence Substitutions in the APR Have Decreased Stability and Decreased Aggregation Propensity.** To determine how sequence alterations in the APR of D76N-β2m affect protein stability and aggregation propensity, six of the variants with an enhanced in vivo growth score were cloned, expressed, and purified, creating the proteins D76N_F62P-, D76N_Y63D-, D76N_L64D-, D76N_L64P-, and D76N_L65β2m. These variants span the APR and include the four sequence substitutions with the highest in vivo growth scores at each site from the TPBLA, along with the two designed variants, D76N_L64D- and D76N_L65β2m, which were predicted to be highly aggregation resilient but not severely destabilized using Solubis (SI Appendix, Fig. S12). The stability (Tm.app) for the six variants was determined, while only four of the variants could be purified in an amount sufficient for analysis of their aggregation rate (T_half) (D76N_L65K-, D76N_F62P-, D76N_Y63D-, and D76N_L64D-β2m) (SI Appendix, Materials and Methods, Fig. 5 C and D and SI Appendix, Table S8 and Fig. S13). Surprisingly, and in contrast with predictions based on Solubis (21, 22) (SI Appendix, Fig. S12) and previous predictions (S2)—which suggest, in general, that reducing aggregation comes with the cost of destabilizing a protein—several counterexamples were found for D76N-β2m. For example, using Solubis, D76N_L64D-β2m is predicted to abolish the APR (21, 22) (SI Appendix, Fig. S12) by adding a gatekeeper residue in the middle of the APR (cutting the APR in two), but the aggregation rate (T_half) of this variant is only marginally longer than that of D76N-β2m (Fig. 5 D and SI Appendix, Fig. S13C). Moreover, D76N_F62P- and D76N_Y63D-β2m have similar stability as D76N-β2m (Fig. 5 C and SI Appendix, Fig. S13 A and B), yet Solubis predicts these mutations to be destabilizing (SI Appendix, Fig. S12). Finally, only one mutation (L65K) was found to abolish aggregation (Fig. 5 C and SI Appendix, Fig. S13 D), in agreement with Solubis and previous results. The error bar in the fitting error (D) (SI Appendix, Fig. S12) by adding a gatekeeper residue in the middle of the APR (cutting the APR in two), but the aggregation rate (T_half) of this variant is only marginally longer than that of D76N-β2m (Fig. 5 D and SI Appendix, Fig. S13C). Moreover, D76N_F62P- and D76N_Y63D-β2m have similar stability as D76N-β2m (Fig. 5 C and SI Appendix, Fig. S13 A and B), yet Solubis predicts these mutations to be destabilizing (SI Appendix, Fig. S12). Finally, only one mutation (L65K) was found to abolish aggregation (Fig. 5 C and SI Appendix, Fig. S13 D).
(21, 22) (SI Appendix, Fig. S12). These results highlight the complexity of predicting the effect of a mutation on aggregation, which we show depends on a critical balance of native-state stability, solubility, the presence of the APR in the sequence, and the properties of nonnative states that are formed at different stages of the aggregation cascade (SI Appendix, Fig. S14).

Finally, to determine whether amino acid substitutions in the APR of D76N-β2m have a similar effect on the WT protein, the six sequence alterations in the APR of D76N-β2m discussed above were introduced into WT-β2m, and the in vivo growth score of each was determined using the TPBLA. Strikingly, the results revealed that the effects of the amino acid substitutions are different for WT- and D76N-β2m, dependent on the site of substitution and the identity of the residue introduced (SI Appendix, Fig. S15). In WT-β2m, three of the variants in the APR increased the in vivo growth score (F62P, Y63D, and L65K), one had little effect (L64D), and two reduced the score (L64P and L65P). By contrast, all six variants increased the in vivo growth score of D76N-β2m. This suggests a difference in the stability/aggregation tradeoff and/or differences in the mechanisms of aggregation of the two proteins, despite the fact that the proteins differ by only a single amino acid substitution in a solvent-exposed loop that is distant in sequence and space to residues in the APR.

Natural Evolution of β2m Sequences. We next wondered whether the APR of β2m is conserved among species, especially given that this sequence appears to drive aggregation of D76N-β2m. Analysis of 262 sequences of β2m from animals throughout Mammalia showed that residues in the APR (particularly Trp60, Phe62, Tyr63, Leu64, and Leu65) and Asp76 are highly conserved (SI Appendix, Fig. S16 A–C). With 100% identity across all 262 sequences, Trp60 and Phe62 form key contacts with the MHC 1 heavy chain, which is vital for its function (34). Leu64 (88% identity) forms part of the hydrophobic core of the protein, suggesting that this residue may be beneficial for stability, while Leu65 (100% conserved) is solvent exposed and may be important for folding rather than for stability or function. A total of 16 amino acid substitutions were found in the APR in these 262 sequences (0 substitutions at positions 60, 62, and 65; three substitutions at position 61; four substitutions at position 63; and five substitutions at positions 64 and 66). As we show above, residue 76 plays a unique role in determining the aggregation of human β2m (Fig. 3). Position 76 is Asp in 96% of the 262 mammalian sequences of β2m (SI Appendix, Fig. S16C). Six substitutions are observed at residue 76 (Ala, His, Asn, Ser, Thr, and Val). Interestingly, saturation mutagenesis of residue 76 showed that these six substitutions are among those that have the least effect on the in vivo growth score and on protein stability compared with Asp76 (Figs. 3A and 4A).

One β2m sequence was found (European rabbit) that contains an Asn at position 76 and retains a strong APR involving residues 60 to 66 (60WSFYLLV66), which differs from human β2m only at residue 66. To determine whether rabbit-β2m is as aggregation prone as its sequence might predict, the protein was expressed and purified, and its rate of aggregation, stability, and in vivo growth score were determined. Surprisingly, the results revealed that rabbit-β2m is more resilient to aggregation than human D76N-β2m, with a high in vivo growth score, a similar Tm(app) to human D76N-β2m, and little or no aggregation over 100 h (SI Appendix, Fig. S16 D–F). Thus, even with an Asn at position 76 and a strong APR, the sequence of rabbit β2m must have evolved other means of preventing aggregation.

Discussion

The TPBLA has been used previously to select for proteins with increased kinetic and thermodynamic stability (29, 30); to rank the aggregation propensity of amyloidogenic peptides (28); to screen for small-molecule inhibitors of protein aggregation (28); and, most recently, to evolve antibody fragments for increased aggregation resistance (27). Here, we have exploited the powers of the TPBLA to investigate the relationship among sequence, stability, and aggregation of the amyloidogenic protein D76N-β2m. This protein was selected for our study as its aggregation mechanism is complex, commencing from an initially stably structured protein with an all-antiparallel immunoglobulin fold, which presumably must reorganize substantially during formation of the cross-β structure of amyloid (4). The protein has also been shown to differ in its aggregation mechanism from WT-β2m (31, 39), despite the proteins differing by only a single amino acid in a solvent-exposed loop (15). Finally, previous studies of aggregation of WT-β2m under acidic conditions have shown that there is no relationship between aggregation rate and thermodynamic stability (36), suggesting that the high aggregation propensity of D76N-β2m cannot be rationalized by the protein’s reduced global stability alone.

The results presented here highlight the ability of the TPBLA to differentiate the behavior of β2m variants that differ by only a single residue, opening the door to the use of the assay to select for D76N-β2m sequence variants with enhanced properties. Firstly, using saturation mutagenesis at three different positions that each target a solvent-exposed Asp (residues 53, 76, and 98), we used the TPBLA to reveal the unique importance of residue 76 in defining the aggregation of β2m. The native Asp was most protective, Glu and Ala showed some protection, and all other residues (including Asn) resulted in a low in vivo growth score when introduced at this site. In marked contrast, there is no effect of amino acid substitution at residue 98, while residue 53 revealed behavior that is entirely consistent with its location in an edge strand (46).

The potential of a folded protein to assemble into amyloid fibrils depends on a complex combination of interdependent characteristics, each of which is affected by the protein sequence. These include properties of the native protein, such as thermodynamic and kinetic stability, solubility, cooperativity of the native fold, and the solvent accessibility of its usually buried APR(s) (52). The properties of the protein sequence—such as its inherent solubility; β-sheet propensity; the presence of APRs; and the type of residues that flank an APR, such as gatekeeper residues (Glu, Lys, Arg, Asp, and Pro) that suppress aggregation—also play a key role in determining whether a protein aggregates under a defined set of solution conditions (45). Aggregation may also be initiated from the native state; a structured, but nonnative, conformation (such as the I3-state for WT-β2m; ref. 41); the unfolded state; or a combination of these different species. As a consequence, predicting whether a folded protein will self-assemble into amyloid fibrils under a defined set of conditions remains challenging (3). Here, using the TPBLA to evolve sequence variants of D76N-β2m with higher in vivo growth scores, we show that the assay detects the “limiting factor” or “Achilles heel” of the protein sequence (i.e., the property that is least evolved and places the protein at the threshold of aggregation). Such residues make the protein hypersensitive to sequence alterations at that site. Saturation mutagenesis revealed that the in vivo growth score of β2m is sensitive to the identity of residue 76, with two other solvent-exposed sites in the protein (residues 53 and 98) displaying
strikingly different behavior. The results also demonstrate the power of the TPBLA to reveal hotspots in a protein sequence that may cause its aggregation/insolubility and to select for sequence variants at different sites with improved properties. For the 20 D76X-β2m variants, a “sweet spot” between protein stability and aggregation was revealed, with the D76N variant aggregating rapidly in vitro, while proteins that are destabilized or stabilized relative to D76N-β2m aggregate more slowly, at least under the conditions explored here. Similar concepts of proteins at the “knife edge” have been described previously, in which protein stability and expression levels in vivo are critically balanced relative to their aggregation propensity (46, 53, 54).

In vivo evolution of D76N-β2m using the TPBLA confirmed the unique importance of residue 76 in determining the high aggregation propensity of this protein relative to WT-β2m, since sequences that revert Asn to the WT Asp were commonly detected (notably, the only other [one copy] substitution at this site was D76S; SI Appendix, Table S6). All other amino acid substitutions that improved the properties of D76N-β2m involved residues that lie in the APR (60WSFYLLY66), highlighting the dual importance of the identity of residue 76 and the APR in determining D76N-β2m aggregation. In silico analysis of the amino acid substitutions within the APR selected to improve the properties of D76N-β2m (using Solubis; ref. 21, 22) predict that 41% of the sequence changes that reduce the aggregation propensity of the APR (as judged by Tango; ref. 18) will also reduce protein stability (using FoldX; ref. 17) (SI Appendix, Fig. S12). This prediction is consistent with previous results that suggest that the presence of APRs is maintained in evolution since such regions stabilize a protein’s fold, but bring the associated cost that aggregation propensity is increased (52). In practice, however, the situation for D76N-β2m is more complex, with some substitutions in the APR having little effect on stability (e.g., F62P and Y63D), while others reduce stability (e.g., L64D, L64P, L65K, and L65P), and some reduce aggregation (e.g., F62P and L65K), while others have little effect (e.g., L64D) (Fig. 5 C and D).

Another striking finding from our study is that variants in the APR that enhance the properties of D76N-β2m have different effects on WT-β2m (SI Appendix, Fig. S15), consistent with the proteins aggregating by distinct molecular mechanisms despite differing by only a single residue (31). This suggests that residues in the APR that are important for aggregation must be enhanced by the presence of an Asn at residue 76, despite its distal location. This effect could be intramolecular (e.g., by affecting the propensity to expose the APR in nonnative monomers) or via Asn76 enhancing the population of on-pathway oligomers required for aggregation; SI Appendix, Fig. S14). Destabilization of kinetically trapped oligomers or the diversion of off-pathway oligomers toward more assembly-competent species would also give rise to the observed increased rate of amyloid formation of the D76N-β2m variant. Such mechanisms cannot be teased apart by the data presented here, and would require analysis of the effect of mutation on the structure and stability of oligomers and fibrils themselves (SI Appendix, Fig. S14). The findings that the amyloidogenicity of D76N-β2m cannot be rationalized by its reduced thermodynamic stability alone and that rabbit β2m does not aggregate in vitro under the conditions employed, despite having an Asn at residue 76, a highly conserved APR—and similar thermodynamic stability to D76N-β2m—highlights the importance of other residues in determining the amyloidogenicity of the protein via mechanisms that remain obscure.

Folded proteins that aggregate into amyloid can be divided into two classes: proteins that require global unfolding in order to initiate amyloid formation, as has been shown for antibody light chains (55, 56) and TTR (57); and proteins for which a specific partially folded species is required for aggregation to proceed (as shown for WT-β2m and ΔN6-β2m; ref. 41). The detailed molecular mechanism(s) by which the all-antiparallel β-sheet structure of native D76N-β2m is transformed into the cross-β structure of amyloid remain(s) unclear (31). One plausible mechanism could involve partial unfolding to a species that enables unzipping of the native β-strands and reorientation of the disulfide bond linking Cys25 to Cys80, akin to the mechanism proposed for amyloidogenic light chains (58). Since global stability, measured using thermal denaturation, does not correlate with the T_{half} of aggregation for the D76N-β2m variants analyzed here, global unfolding is an unlikely prerequisite of D76N-β2m aggregation. Previous results have shown that the formation of the structured I_{β}-state is required to initiate the aggregation of WT- and ΔN6-β2m (41, 59, 60), yet amyloid formation of D76N-β2m does not depend on the formation of this state (31). Instead, we propose that one or more nonnative species that critically involve the APR and Asn76 are required to initiate amyloid formation of D76N-β2m. Such a model would rationalize the importance of both the APR and Asn76 for rapid aggregation, as well as the distinct aggregation mechanisms of the WT- and D76N-β2m variants. Further work will be needed to solve the structure of D76N-β2m amyloid fibrils and to explore the nature of the initiating steps in D76N-β2m aggregation so as to better understand how apparently innocuous sequence changes can have such a profound effect on the ability of this protein to aggregate into amyloid and cause disease.

Materials and Methods

TPBLA assay, molecular biology, protein expression, protein purification, in vitro fibration assays, negative-stain EM (electron microscopy), thermal denaturation monitored by far-UV CD, equilibrium unfolding experiments monitored by fluorescence, prediction algorithms of stability solubility and amyloid propensity, crystallography, creation of the β2m D76N-β2m library, directed evolution and selection of β2m variants using the TPBLA, prediction of the protein stability and protein aggregation using Solubis, and sequence alignment are described in detail in SI Appendix.

Data Availability. All raw data for figures have been deposited to the University of Leeds DOI site (https://doi.org/10.5518/1073). All study data are included in the article and/or SI Appendix (62).

ACKNOWLEDGMENTS. We thank our research groups for helpful discussions and Nasir Khan for excellent technical support. S.E.R., N.G., R.M.M., and Y.X. are funded by Wellcome (204963). We thank Hugh Smith for his help in the beginning of the project. We are also grateful to the University of Leeds, the Biological and Biotechnology Research Council (BBSRC) (BB/M012573/1), and Wellcome (094232) for funding for CD, X-ray, MS (mass spectrometry), and EM Facilities.
