Source Coding for Quasiarithmetic Penalties

Michael B. Baer, Member, IEEE

Abstract

Huffman coding finds a prefix code that minimizes mean codeword length for a given probability distribution over a finite number of items. Campbell generalized the Huffman problem to a family of problems in which the goal is to minimize not mean codeword length \( \sum_i p_i l_i \) but rather a generalized mean of the form \( \varphi^{-1}(\sum_i p_i \varphi(l_i)) \), where \( l_i \) denotes the length of the \( i \)th codeword, \( p_i \) denotes the corresponding probability, and \( \varphi \) is a monotonically increasing cost function. Such generalized means — also known as quasiarithmetic or quasilinear means — have a number of diverse applications, including applications in queueing. Several quasiarithmetic-mean problems have novel simple redundancy bounds in terms of a generalized entropy. A related property involves the existence of optimal codes: For “well-behaved” cost functions, optimal codes always exist for (possibly infinite-alphabet) sources having finite generalized entropy. Solving finite instances of such problems is done by generalizing an algorithm for finding length-limited binary codes to a new algorithm for finding optimal binary codes for any quasiarithmetic mean with a convex cost function. This algorithm can be performed using quadratic time and linear space, and can be extended to other penalty functions, some of which are solvable with similar space and time complexity, and others of which are solvable with slightly greater complexity. This reduces the computational complexity of a problem involving minimum delay in a queue, allows combinations of previously considered problems to be optimized, and greatly expands the space of problems solvable in quadratic time and linear space. The algorithm can be extended for purposes such as breaking ties among possibly different optimal codes, as with bottom-merge Huffman coding.

Source Coding for Quasiarithmetic Penalties

I. INTRODUCTION

It is well known that Huffman coding [1] yields a prefix code minimizing expected length for a known finite probability mass function. Less well known are the many variants of this algorithm that have been proposed for related problems [2]. For example, in his doctoral dissertation, Humblet discussed two problems in queueing that have nonlinear terms to minimize [3]. These problems, and many others, can be reduced to a certain family of generalizations of the Huffman problem introduced by Campbell in [4].

In all such source coding problems, a source emits symbols drawn from the alphabet \( X = \{1, 2, \ldots, n\} \), where \( n \) is an integer (or possibly infinity). Symbol \( i \) has probability \( p_i \), thus defining probability mass function \( p \).

We assume without loss of generality that \( p_i > 0 \) for every \( i \in X \), and that \( p_i \leq p_j \) for every \( i > j \) \((i,j \in X)\).

The source symbols are coded into codewords composed of symbols of the \( D \)-ary alphabet \( \{0, 1, \ldots, D-1\} \), most often the binary alphabet, \( \{0, 1\} \). The codeword \( c_i \) corresponding to symbol \( i \) has length \( l_i \), thus defining length distribution \( l \). Finding values for \( l \) is sufficient to find a corresponding code.

Huffman coding minimizes \( \sum_{i \in X} p_i l_i \). Campbell’s formulation adds a continuous (strictly) monotonic increasing cost function \( \varphi(l) : \mathbb{R}_+ \to \mathbb{R}_+ \). The value to minimize is then

\[
L(p, l, \varphi) \triangleq \varphi^{-1} \left( \sum_{i \in X} p_i \varphi(l_i) \right). \tag{1}
\]

Campbell called \( L \) the “mean length for the cost function \( \varphi \)”; for brevity, we refer to it, or any value to minimize, as the penalty. Penalties of the form \( \varphi \) are called quasiarithmetic or quasilinear; we use the former term in order to avoid confusion with the more common use of the latter term in convex optimization theory.

Note that such problems can be mathematically described if we make the natural coding constraints explicit: the integer constraint, \( l_i \in \mathbb{Z}_+ \), and the Kraft (McMillan) inequality [5],

\[
\kappa(l) \triangleq \sum_{i \in X} D^{-l_i} \leq 1.
\]

Given these constraints, examples of \( \varphi \) in (1) include a quadratic cost function useful in minimizing delay due to queueing and transmission,

\[
\varphi(x) = \alpha x + \beta x^2 \tag{2}
\]

for nonnegative \( \alpha \) and \( \beta \) [6], and an exponential cost function useful in minimizing probability of buffer overflow, \( \varphi(x) = D^{tx} \) for positive \( t \) [3], [7]. These and other examples are reviewed in the next section.

Campbell noted certain properties for convex \( \varphi \), such as those examples above, and others for concave \( \varphi \). Strictly concave \( \varphi \) penalize shorter codewords more harshly than the linear function and penalize longer codewords less harshly. Conversely, strictly convex \( \varphi \) penalize longer codewords more harshly than the linear function and penalize shorter codewords less harshly. Convex \( \varphi \) need not yield convex \( L \), although \( \varphi(L) \) is clearly convex if and only if \( \varphi \) is. Note that one can map decreasing \( \varphi \) to a corresponding increasing function \( \tilde{\varphi}(l) = \varphi_{\max} - \varphi(l) \) without changing the value of \( L \) (e.g., for \( \varphi_{\max} = \varphi(0) \)). Thus the restriction to
increasing $\varphi$ can be trivially relaxed.

We can generalize $L$ by using a two-argument cost function $f(l, p)$ instead of $\varphi(l)$, as in [3], and adding $\{\infty\}$ to its range. We usually choose functions with the following property:

Definition 1: A cost function $f(l, p)$ and its associated penalty $\tilde{L}$ are differentially monotonic if, for every $l > 1$, whenever $f(l - 1, p_i)$ is finite and $p_i > p_j$, $f(l, p_i) - f(l - 1, p_i) > f(l, p_j) - f(l - 1, p_j)$.

This property means that the contribution to the penalty of an $l$th bit in a codeword will be greater if the corresponding event is more likely. Clearly any $f(l, p) = p_i \varphi(l)$ will be differentially monotonic. This restriction on the generalization will aid in finding algorithms for coding such cost functions, which we denote as generalized quasiarithmetic penalties:

Definition 2: Let $f(l, p) : \mathbb{R}_+ \times [0, 1] \to \mathbb{R}_+ \cup \{\infty\}$ be a function nondecreasing in $l$. Then

$$\tilde{L}(p, l, f) \triangleq \sum_{i \in X} f(l_i, p_i). \quad (3)$$

is called a generalized quasiarithmetic penalty. Further, if $f$ is convex in $l$, it is called a generalized quasiarithmetic convex penalty.

As indicated, quasiarithmetic penalties — mapped with $\varphi$ using $f(l_i, p_i) = p_i \varphi(l_i)$ to $\tilde{L}(p, l, f) = \varphi(L(p, l, \varphi))$ — are differentially monotonic, and thus can be considered a special case of differentially monotonic generalized quasiarithmetic penalties.

In this paper, we seek properties of and algorithms for solving problems of this form, occasionally with some restrictions (e.g., to convexity of $\varphi$). In the next section, we provide examples of the problem in question. In Section III we investigate Campbell’s quasiarithmetic penalties, expanding beyond Campbell’s properties for a certain class of $\varphi$ that we call subtranslatory. This will extend properties — entropy bounds, existence of optimal codes — previously known only for linear $\varphi$ and, in the case of entropy bounds, for $\varphi$ of the exponential form $\varphi(x) = D^a x$. These properties pertain both to finite and infinite input alphabets, and some are applicable beyond subtranslatory penalties. We then turn to algorithms for finding an optimal code for finite alphabets in Section IV we start by presenting and extending an alternative to code tree notation, nodeset notation, originally introduced in [6]. Along with the Coin Collector’s problem, this notation can aid in solving coding problems with generalized quasiarithmetic convex penalties. We explain, prove, and refine the resulting algorithm, which is $O(n^2)$ time and $O(n)$ space when minimizing for a differentially monotonic generalized quasiarithmetic penalty; the algorithm can be extended to other penalties with a like or slightly greater complexity.

This is an improvement, for example, on a result of Larmore, who in [6] presented an $O(n^3)$-time $O(n^3)$-space algorithm for cost function (2) in order to optimize a more complicated penalty related to communications delay. Our result thus improves overall performance for the quadratic problem and offers an efficient solution for the more general convex quasiarithmetic problem. Conclusions are presented in Section V.

II. Examples

The additive convex coding problem considered here is quite broad. Examples include

$$f(l_i, p_i) = p_i l_i^a \quad (\varphi(x) = x^a)$$

for $a \geq 1$, the moment penalty; see, e.g., [8, pp. 121–122]. Although efficient solutions have been given for $a = 1$ (the Huffman case) and $a = 2$ (the quadratic moment), no polynomial-time algorithms have been proposed for the general case.
The quadratic moment was considered by Larmore in [6] as a special case of the quadratic problem, which is perhaps the case of greatest relevance. Restating this problem in terms of \( f \),

\[
f(l_i, p_i) = p_i(\alpha x + \beta x^2)
\]

This was solved with cubic space and time complexity as a step in solving a problem related to message delay. This larger problem, treated first by Humblet [3] then Flores [9], was solved with an algorithm that can be altered to become an \( O(t) \) for \( t < \infty \) function, it is notable as corresponding to one of the simplest convex-cost penalties of the form (3).

Although the author knows of no use for this particular cost function, it is notable as corresponding to one of the known applications — and penalties which result from combining these problems — one might want to solve for a different utility function in order to find a compromise among these applications or another trade-off of codeword lengths. These functions need not be like Campbell’s in that they need not be linear in \( p \); for example, consider

\[
f(l_i, p_i) = (1 - p_i)^{-l_i}.
\]

Although the author knows of no use for this particular cost function, it is notable as corresponding to one of the simplest convex-cost penalties of the form (5).
III. Properties

A. Bounds and the Subtranslatory Property

Campbell’s quasi-arithmetic penalty formulation can be restated as follows:

Given $p = (p_1, \ldots, p_n)$, $p_i > 0$, $\sum_i p_i = 1$;
convex, monotonically increasing
$\varphi : \mathbb{R}_+ \rightarrow \mathbb{R}_+$
Minimize $\{ l \}$ $L(p, l, \varphi) = \sum_i p_i \varphi(l_i)$
subject to $\sum_i 2^{-l_i} \leq 1$
$l_i \in \mathbb{Z}_+$
(7)

In the case of linear $\varphi$, the integer constraint is often removed to obtain bounds related to entropy, as we do in the nonlinear case:

Given $p = (p_1, \ldots, p_n)$, $p_i > 0$, $\sum_i p_i = 1$;
convex, monotonically increasing
$\varphi : \mathbb{R}_+ \rightarrow \mathbb{R}_+$
Minimize $\{ l \}$ $L(p, l, \varphi) = \sum_i p_i \varphi(l_i)$
subject to $\sum_i 2^{-l_i} \leq 1$
(8)

Note that, given $p$ and $\varphi$, $L^\dagger$, the minimum for the relaxed (real-valued) problem (8), will necessarily be less than or equal to $L^*$, the minimum for the original (integer-constrained) problem (7). Let $L^\dagger$ and $L^*$ be corresponding minimizing values for the relaxed and constrained problems, respectively. Restating, and adding a fifth definition:

$$L^* \triangleq \min_{\sum_i 2^{-l_i} \leq 1, l_i \in \mathbb{Z}_+} L(p, l, \varphi)$$

$$L^\dagger \triangleq \min_{l_i \in \mathbb{R}} L(p, l, \varphi)$$

$$l^* \triangleq \arg \min_{\sum_i 2^{-l_i} \leq 1, l_i \in \mathbb{Z}_+} L(p, l, \varphi)$$

$$l^\dagger \triangleq \arg \min_{l_i \in \mathbb{R}} L(p, l, \varphi)$$

$$l^\dagger \triangleq ([l^\dagger_1], [l^\dagger_2], \ldots, [l^\dagger_n])$$

This is a slight abuse of arg min notation since $L^*$ could have multiple corresponding optimal length distributions ($l^*$). However, this is not a problem, as any such value will suffice. Note too that $l^\dagger$ satisfies the Kraft inequality and the integer constraint, and thus $L(p, l^\dagger, \varphi) \geq L^*$.

We obtain bounds for the optimal solution by noting that, since $\varphi$ is monotonically increasing,

$$\varphi^{-1} \left( \sum_i p_i \varphi(l_i^\dagger) \right) \leq \varphi^{-1} \left( \sum_i p_i \varphi(l_i^*) \right) \leq \varphi^{-1} \left( \sum_i p_i \varphi(l_i^\dagger + 1) \right)$$

(9)

These bounds are similar to Shannon redundancy bounds for Huffman coding. In the linear/Shannon case, $l_i^\dagger = -\log_2 p_i$, so the last expression is $\sum_i p_i (l_i^\dagger + 1) = 1 + \sum_i p_i l_i^\dagger = 1 + H(p)$, where $H(p)$ is the Shannon entropy, so $H(p) \leq \sum_i p_i l_i^* < 1 + H(p)$. These Shannon bounds can be extended to quasi-arithmetic problems by first defining $\varphi$-entropy as follows:

**Definition 3:** Generalized entropy or $\varphi$-entropy is

$$H(p, \varphi) \triangleq \inf_{\sum_i 2^{-l_i} \leq 1} L(p, l, \varphi)$$

(10)

where here infimum is used because this definition applies to codes with infinite, as well as finite, input alphabets [4].

Campbell defined this as a generalized entropy [4]; we go further, by asking which cost functions, $\varphi$, have
the following property:

\[ H(p, \varphi) \leq L(p, l', \varphi) < 1 + H(p, \varphi) \quad (11) \]

These bounds exist for the exponential case [4] with \( H(p, \varphi) = H_\alpha(p) \), where \( \alpha \equiv (1 + t)^{-1} \), and \( H_\alpha(p) \) denotes Rényi \( \alpha \)-entropy [17]. The bounds extend to exponential costs because they share with the linear costs (and only those costs) a property known as the translatory property, described by Aczél [18], among others:

**Definition 4:** A cost function \( \varphi \) (and its associated penalty) is translatory if, for any \( l \in \mathbb{R}^n_+ \), probability mass function \( p \), and \( c \in \mathbb{R}_+ \),

\[ L(p, l + c, \varphi) = L(p, l, \varphi) + c \]

where \( l + c \) denotes adding \( c \) to each \( l_i \) in \( l \) [18].

We broaden the collection of penalty functions satisfying such bounds by replacing the translatory equality with an inequality, introducing the concept of a subtranslatory penalty:

**Definition 5:** A cost function \( \varphi \) (and its associated penalty) is subtranslatory if, for any \( l \in \mathbb{R}^n_+ \), probability mass function \( p \), and \( c \in \mathbb{R}_+ \),

\[ L(p, l + c, \varphi) \leq L(p, l, \varphi) + c. \]

For such a penalty, (11) still holds.

If \( \varphi \) obeys certain regularity requirements, then we can introduce a necessary and sufficient condition for it to be subtranslatory. Suppose that the invertible function \( \varphi : \mathbb{R}_+ \to \mathbb{R}_+ \) is real analytic over a relevant compact interval. We might choose this interval to be, for example, \( A = [\delta, 1/\delta] \) for some \( \delta \in (0, 1) \). (Let \( \delta \to 0 \) to show the following argument is valid over all \( \mathbb{R}_+ \).) We assume \( \varphi^{-1} \) is also real analytic (with respect to interval \( \varphi(A) \)). Thus all derivatives of the function and its inverse are bounded.

**Theorem 1:** Given real analytic cost function \( \varphi \) and its real analytic inverse \( \varphi^{-1} \), \( \varphi \) is subtranslatory if and only if, for all positive \( l \) and all positive \( p \) summing to 1,

\[ \sum_i p_i \varphi'(l_i) \leq \varphi'( \left( \sum_i p_i \varphi(l_i) \right) ) \quad (12) \]

where \( \varphi' \) is the derivative of \( \varphi \).

**Proof:** First note that, since all values are positive, inequality (12) is equivalent to

\[ \left( \sum_i p_i \varphi'(l_i) \right) \cdot (\varphi^{-1})' \left( \sum_i p_i \varphi(l_i) \right) \leq 1. \quad (13) \]

We show that, when (13) is true everywhere, \( \varphi \) is subtranslatory, and then we show the converse. Let \( \epsilon > 0 \). Using power expansions of the form

\[ g(x) + \epsilon g'(x) = g(x + \epsilon) \pm O(\epsilon^2) \]

on \( \varphi \) and \( \varphi^{-1} \),

\[ \varphi^{-1} \left( \sum_i p_i \varphi(l_i) \right) + \epsilon \]

\[ \geq \varphi^{-1} \left( \sum_i p_i \varphi(l_i) \right) + \epsilon \cdot \left( \sum_i p_i \varphi'(l_i) \right) \cdot (\varphi^{-1})' \left( \sum_i p_i \varphi(l_i) \right) \pm O(\epsilon^2) \]

\[ \varphi^{-1} \left( \sum_i p_i \varphi(l_i) + \epsilon \cdot \sum_i p_i \varphi'(l_i) \right) \pm O(\epsilon^2) \]

\[ \varphi^{-1} \left( \sum_i p_i \varphi(l_i + \epsilon) \right) \pm O(\epsilon^2). \quad (14) \]

Step (a) is due to (13), step (b) due to the power expansion on \( \varphi^{-1} \), step (c) due to the power expansion on \( \varphi \), and step (d) due to the power expansion on \( \varphi^{-1} \) (where the bounded derivative of \( \varphi^{-1} \) allows for the asymptotic term to be brought outside the function).
Next, evoke the above inequality $c/\epsilon$ times:

$$
\varphi^{-1}\left(\sum_i p_i \varphi(l_i + c)\right) \\
\leq \epsilon + \varphi^{-1}\left(\sum_i p_i \varphi(l_i + c - \epsilon)\right) + O(\epsilon^2) \\
\leq \ldots \\
\leq \epsilon \left[\frac{c}{\epsilon}\right] + \varphi^{-1}\left(\sum_i p_i \varphi(l_i) + c - \epsilon \left[\frac{c}{\epsilon}\right]\right) + O(\epsilon) \\
\leq c + \varphi^{-1}\left(\sum_i p_i \varphi(l_i)\right) + O(\epsilon)
$$

Taking $\epsilon \to 0$,

$$
\varphi^{-1}\left(\sum_i p_i \varphi(l_i + c)\right) \leq c + \varphi^{-1}\left(\sum_i p_i \varphi(l_i)\right).
$$

Thus, the fact of (12) is sufficient to know that the penalty is subtranslatory.

To prove the converse, suppose $\sum_i p_i \varphi' (l_i) > \varphi' \left(\varphi^{-1} \left(\sum_i p_i \varphi(l_i)\right)\right)$ for some valid $l$ and $p$. Because $\varphi$ is analytic, continuity implies that there exist $\delta_0 > 0$ and $\epsilon_0 > 0$ such that

$$
\sum_i p_i \varphi' (l'_i) \geq (1 + \delta_0) \cdot \varphi' \left(\varphi^{-1} \left(\sum_i p_i \varphi(l'_i)\right)\right)
$$

for all $l' \in [l, l + \epsilon_0)$. The chain of inequalities above reverse in this range with the additional multiplicative constant. Thus (14) becomes

$$
\varphi^{-1}\left(\sum_i p_i \varphi(l'_i)\right) + (1 + \delta_0) \epsilon \\
\leq \varphi^{-1}\left(\sum_i p_i \varphi(l'_i + \epsilon)\right) + O(\epsilon^2)
$$

for $l' \in [l, l + \epsilon_0)$, and (15) becomes, for any $c \in (0, \epsilon_0)$,

$$
\varphi^{-1}\left(\sum_i p_i \varphi(l_i + c)\right) \\
\geq (1 + \delta_0) c + \varphi^{-1}\left(\sum_i p_i \varphi(l_i)\right) + O(\epsilon)
$$

which, taking $\epsilon \to 0$, similarly leads to

$$
\varphi^{-1}\left(\sum_i p_i \varphi(l_i + c)\right) \\
\geq (1 + \delta_0) c + \varphi^{-1}\left(\sum_i p_i \varphi(l_i)\right) \\
> c + \varphi^{-1}\left(\sum_i p_i \varphi(l_i)\right)
$$

and thus the subtranslatory property fails and the converse is proved.

Therefore, for $\varphi$ satisfying (12), we have the bounds of (11) for the optimum solution. Note that the right-hand side of (12) may also be written $\varphi' \left(L(p, l, \varphi)\right)$; thus (12) indicates that the average derivative of $\varphi$ at the codeword length values is at most the derivative of $\varphi$ at the value of the penalty for those length values.

The linear and exponential penalties satisfy these equivalent inequalities with equality. Another family of cost functions that satisfies the subtranslatory property is $\varphi(l_i) = l_i^a$ for fixed $a \geq 1$, which corresponds to

$$
L(p, l, \varphi) = \left(\sum_i p_i l_i^a\right)^{1/a}.
$$

Proving this involves noting that Lyapunov’s inequality for moments of a random variable yields

$$
\left(\sum_i p_i l_i^{a-1}\right)^{\frac{1}{a-1}} \leq \left(\sum_i p_i l_i^a\right)^{\frac{1}{a}}
$$

which leads to

$$
a \cdot \left(\sum_i p_i l_i^{a-1}\right) \leq a \cdot \left(\sum_i p_i l_i^a\right)^{\frac{a+1}{a}}
$$

which, because $\varphi'(x) = ax^{a-1}$, is

$$
\sum_i p_i \varphi'(l_i) \leq \varphi' \left(\varphi^{-1} \left(\sum_i p_i \varphi(l_i)\right)\right)
$$

the inequality we desire.

Another subtranslatory penalty is the quadratic quasiarithmetic penalty of (2), in which

$$
\varphi(x) = ax + \beta x^2
$$
for $\alpha, \beta \geq 0$. This has already been shown for $\beta = 0$; when $\beta > 0$,
\[
\varphi'(x) = \alpha + 2\beta x
\]
\[
\varphi^{-1}(x) = \sqrt{\left(\frac{\alpha}{2\beta}\right)^2 - \frac{x}{\beta} - \frac{\alpha}{2\beta}}
\]
\[
L(p, l, \varphi) = \sqrt{\left(\frac{\alpha}{2\beta}\right)^2 + \sum_i p_i \left(\frac{\alpha l_i + \beta l_i^2}{\alpha + 2\beta l_i}\right) - \frac{\alpha}{2\beta}}.
\]
We achieve the desired inequality through algebra:
\[
\sum_i p_i l_i^2 \geq \left(\sum_i p_i l_i\right)^2
\]
\[
\alpha^2 + 4\beta \sum_i p_i (\alpha l_i + \beta l_i^2) \geq \left(\sum_i p_i (\alpha + 2\beta l_i)\right)^2
\]
\[
\sqrt{\alpha^2 + 4\beta \sum_i p_i (\alpha l_i + \beta l_i^2)} \geq \sum_i p_i (\alpha + 2\beta l_i)
\]
\[
\varphi'(L(p, l, \varphi)) \geq \sum_i p_i \varphi'(l_i)
\]
We thus have an important property that holds for several cases of interest.

One might be tempted to conclude that every $\varphi$ - or every convex and/or concave $\varphi$ — is subtranslatory. However, this is easily disproved. Consider convex $\varphi(x) = x^3 + 11.1$. Using Cardano’s formula, it is easily seen that (12) does not hold for $p = \left(\frac{1}{4}, \frac{3}{4}\right)$ and $l = \left(\frac{1}{4}, 1\right)$. The subtranslatory test also fails for $\varphi(x) = \sqrt{x}$. Thus we must test any given penalty for the subtranslatory property in order to use the redundancy bounds.

B. Existence of an Optimal Code

Because all costs are positive, the redundancy bounds that are a result of a subtranslatory penalty extend to infinite alphabet codes in a straightforward manner. These bounds thus show that a code with finite penalty exists if and only if the generalized entropy is finite, a property we extend to nonsubtranslatory penalties in the next subsection. However, one must be careful regarding the meaning of an “optimal code” when there are an infinite number of possible codes satisfying the Kraft inequality with equality. Must there exist an optimal code, or can there be an infinite sequence of codes of decreasing penalty without a code achieving the limit penalty value?

Fortunately, the answer is the former, as the existence results of Linder, Tarokh, and Zeger in [19] can be extended to quasiarithmetic penalties. Consider continuous strictly monotonic $\varphi : \mathbb{R}_+ \to \mathbb{R}_+$ (as proposed by Campbell) and $p = (p_1, p_2, \ldots)$ such that
\[
L^*(p, \varphi) \triangleq \inf_{\sum_i p_i l_i \leq 1} \varphi^{-1}\left(\sum_{i=1}^\infty p_i \varphi(l_i)\right)
\]
is finite. Consider, for an arbitrary $n \in \mathbb{Z}_+$, optimizing for $\varphi$ with weights
\[
p^{(n)} \triangleq (p_1, p_2, \ldots, p_n, 0, 0, \ldots).
\]
(We call the entries to this distribution “weights” because they do not necessarily add up to 1.) Denote the optimal code a truncated code, one with codeword lengths
\[
l^{(n)} \triangleq \{l_1^{(n)}, l_2^{(n)}, \ldots, l_n^{(n)}, \infty, \infty, \ldots\}.
\]
Thus, for convenience, $l_i^{(j)} = \infty$ for $i > j$. These lengths are also optimal for $(\sum_{j=1}^n p_j)^{-1} \cdot p^{(n)}$, the distribution of normalized weights.

Following [19], we say that a sequence of codeword length distributions $l^{(1)}, l^{(2)}, l^{(3)}, \ldots$ converges to an infinite prefix code with codeword lengths $l = \{l_1, l_2, \ldots\}$ if, for each $i$, the $i$th length in each distribution in the sequence is eventually $l_i$ (i.e., if each sequence converges to $l_i$).

Theorem 2: Given quasiarithmetic increasing $\varphi$ and $p$ such that $L^*(p, \varphi)$ is finite, the following hold:

1) There exists a sequence of truncated codeword lengths that converges to optimal codeword lengths for $p$; thus the infimum is achievable.
2) Any optimal code for $p$ must satisfy the Kraft inequality with equality.

Proof: Because here we are concerned only with cases in which the first length is at least 1, we may restrict ourselves to the domain $[\varphi^{-1}(p_1, \varphi(1)), \infty)$. Recall

$$L^*(p, \varphi) = \inf_{\sum_{l_i \in Z_+} \leq 1} \varphi^{-1} \left( \sum_{i=1}^{\infty} p_i \varphi(l_i) \right) < \infty.$$ 

Then there exists near-optimal $l' = \{l'_1, l'_2, l'_3, \ldots \} \in Z_+^\infty$ such that

$$\varphi^{-1} \left( \sum_{i=1}^{\infty} p_i \varphi(l'_i) \right) < L^*(p, \varphi) + 1$$

and thus, for any integer $n$,

$$\varphi^{-1} \left( \sum_{i=1}^{n} p_i \varphi(l'_i) \right) < L^*(p, \varphi) + 1$$

So, using this to approximate the behavior of a minimizing $l^{(n)}$, we have

$$\varphi^{-1} \left( \sum_{i=1}^{n} p_i \varphi(l^{(n)}_i) \right) \leq \varphi^{-1} \left( \sum_{i=1}^{n} p_i \varphi(l'_i) \right) < L^*(p, \varphi) + 1$$

yielding an upper bound on terms

$$p_j \varphi(l^{(n)}_j) \leq \sum_{i=1}^{n} p_i \varphi(l^{(n)}_i) < \varphi \left( L^*(p, \varphi) + 1 \right)$$

for all $j$. This implies

$$l^{(n)}_j < \varphi^{-1} \left( \varphi \left( L^*(p, \varphi) + 1 \right) \right)$$

Thus, for any $i \in Z_+$, the sequence $l^{(1)}_i, l^{(2)}_i, l^{(3)}_i, \ldots$ is bounded for all $l^{(j)}_i \neq \infty$, and thus has a finite set of values (including $\infty$). It is shown in [19] that this suffices for the desired convergence, but for completeness a slightly altered proof follows.

Because each sequence $l^{(1)}_i, l^{(2)}_i, l^{(3)}_i, \ldots$ has a finite set of values, every infinite indexed subsequence for a given $i$ has a convergent subsequence. An inductive argument implies that, for any $k$, there exists a subsequence indexed by $n^k_j$ such that $l^{(n^k_j)}_i, l^{(n^k_j)}_i, l^{(n^k_j)}_i, \ldots$ converges for all $i \leq k$, where $l^{(n^k_1)}_i, l^{(n^k_2)}_i, l^{(n^k_3)}_i, \ldots$ is a subsequence of $l^{(n^k_1')}_i, l^{(n^k_2')}_i, l^{(n^k_3')}_i, \ldots$ for $k' \leq k$. Codeword length distributions $l^{(n)}_1, l^{(n)}_2, l^{(n)}_3, \ldots$ (which we call $l^{(n)}_1, l^{(n)}_2, l^{(n)}_3, \ldots$) thus converge to the codeword lengths of an infinite code $\hat{C}$ with codeword lengths $\hat{l} = \{\hat{l}_1, \hat{l}_2, \hat{l}_3, \ldots \}$. Clearly each codeword length distribution satisfies the Kraft inequality. The limit does as well then; were it exceeded, we could find $i'$ such that

$$\sum_{i=1}^{i'} D_{\hat{l}_i} > 1$$

and thus $n'$ such that

$$\sum_{i=1}^{i' n'} D_{\hat{l}_i} > 1$$

causing a contradiction.

We now show that $\hat{C}$ is optimal. Let $\{\lambda_1, \lambda_2, \lambda_3, \ldots \}$ be the codeword lengths of an arbitrary prefix code. For every $k$, there is a $j \geq k$ such that $\hat{l}_i = l^{(n_\lambda)}_i$ for any $i \leq k$ if $m \geq j$. Due to the optimality of each $l^{(n)}$, for all $m \geq j$:

$$\sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i) \leq \sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i) \leq \sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i) \leq \sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i)$$

and, taking $k \to \infty$, $\sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i) \leq \sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i)$, leading directly to $\varphi^{-1} \left( \sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i) \right) \leq \varphi^{-1} \left( \sum_{i=1}^{k} p_i \varphi(l^{(n_\lambda)}_i) \right)$ and the optimality of $\hat{C}$.

Suppose the Kraft inequality is not satisfied with equality for optimal codeword lengths $\hat{l} = \{\hat{l}_1, \hat{l}_2, \ldots \}$. We can then produce a strictly superior code. There is a $k \in Z_+$ such that $D_{\hat{l}_i} + 1 + \sum_{i=1}^{k} D_{\hat{l}_i} \leq 1$. Consider code $\{\hat{l}_1, \hat{l}_2, \ldots, \hat{l}_{k-1}, \hat{l}_k - 1, \hat{l}_{k+1}, \hat{l}_{k+2}, \ldots \}$. This code satisfies the Kraft inequality and has
penalty \( \varphi^{-1} \left( \sum_i p_i \varphi(l_i) + p_k (\varphi(\hat{l}_k) - \varphi(\hat{l}_k)) \right) < \varphi^{-1} \left( \sum_i p_i \varphi(l_i) \right) \). Thus \( \hat{l} \) is not optimal. Therefore the Kraft inequality must be satisfied with equality for optimal infinite codes.

Note that this theorem holds not just for subtranslatory penalties, but for any quasiarithmetic penalty.

C. Finiteness of Penalty for an Optimal Code

Recall the definition of (10).

\[ H(p, \varphi) = \inf_{\sum_{l_i \in \mathbb{R}_+} \varphi^{-1} \left( \sum_i p_i \varphi(l_i) \right)} \]

for \( \varphi : \mathbb{R}_+ \to \mathbb{R}_+ \).

**Theorem 3:** If \( H(p, \varphi) \) is finite and either \( \varphi \) is subtranslatory or \( \varphi(x + 1) = O(\varphi(x)) \) (which includes all concave and all polynomial \( \varphi \)), then the coding problem of (16).

\[ L^*(p, \varphi) = \inf_{\sum_{l_i \in \mathbb{R}_+} \varphi^{-1} \left( \sum_i p_i \varphi(l_i) \right)} \]

has a minimizing \( l^* \) resulting in a finite value for \( L^*(p, \varphi) \).

**Proof:** If \( \varphi \) is subtranslatory, then \( L^*(p, \varphi) < 1 + H(p, \varphi) < \infty \). If \( \varphi(x + 1) = O(\varphi(x)) \), then there are \( \alpha, \beta > 0 \) such that \( \varphi(x + 1) < \alpha + \beta \varphi(x) \) for all \( x \). Then

\[ \varphi^{-1} \left( \sum_i p_i \varphi(l_i + 1) \right) < \varphi^{-1} \left( \sum_i p_i (\alpha + \beta \varphi(l_i)) \right) \]

\[ = \varphi^{-1} \left( \alpha + \beta \sum_i p_i \varphi(l_i) \right). \]

So

\[ L^*(p, \varphi) < L(p, l^1 + 1, \varphi) < \varphi^{-1} (\alpha + \beta \varphi (H(p, \varphi))) < \infty \]

and the infimum, which we know to also be a minimum, is finite.

IV. ALGORITHMS

A. Nodeiset Notation

We now examine algorithms for finding minimum penalty codes for convex cases with finite alphabets. We first present a notation for codes based on an approach of Larmore [6]. This notation is an alternative to the well known code tree notation, e.g., [20], and it will be the basis for an algorithm to solve the generalized quasiarithmetic (and thus Campbell’s quasiarithmetic) convex coding problem.

In the literature nodeiset notation is generally used for binary alphabets, not for general alphabet coding. Although we briefly sketch how to adapt this technique to general output alphabet coding at the end of Subsection IV-E, an approach fully explained in [21], until then we concentrate on the binary case (\( D = 2 \)).

The key idea: Each node \((i, l)\) represents both the share of the penalty \( L(p, l, f) \) (weight) and the share of the Kraft sum \( \kappa(l) \) (width) assumed for the \( i \)th bit of the \( f \)th codeword. If we show that total weight is an increasing function of the penalty and show a one-to-one correspondence between optimal nodeisets and optimal codes, we can reduce the problem to an efficiently solvable problem, the Coin Collector’s problem.

In order to do this, we first assume bounds on the maximum codeword length of possible solutions, e.g., the maximum unary codeword length of \( n - 1 \). Alternatively, bounds might be explicit in the definition of the problem. Consider for example the length-limited coding problems of (5) and (6), upper bounded by \( l_{\text{max}} \). A third possibility is that maximum length may be implicit in some property of the set of optimal solutions [22]–[24]; we explore this in Subsection IV-E.

We therefore restrict ourselves to codes with \( n \) codewords, none of which has greater length than \( l_{\text{max}} \), where
l_{\text{max}} \in [\lceil \log_2 n \rceil, n-1]. With this we now introduce the nodeset notation for binary coding:

Definition 6: A node is an ordered pair of integers (i, l) such that i \in \{1, \ldots, n\} and l \in \{1, \ldots, l_{\text{max}}\}. Call the set of all nl_{\text{max}} possible nodes I. Usually I is arranged in a grid; see example in Fig. 1. The set of nodes, or nodeset, corresponding to item \(i\) (assigned codeword \(c_i\) with length \(l_i\)) is the set of the first \(l_i\) nodes of column \(i\), that is, \(\eta(i) \triangleq \{(j, l) \mid j = i, l \in \{1, \ldots, l_i\}\}\). The nodeset corresponding to length distribution \(l\) is \(\eta(l) \triangleq \bigcup_i \eta(i)\); this corresponds to a set of \(n\) codewords, a code. We say a node \((i, l)\) has width \(\rho(i, l) \triangleq 2^{-l}\) and weight \(\mu(i, l) \triangleq f(l, p_i) - f(l-1, p_i)\), as in the example in Fig. 1.

If \(I\) has a subset \(N\) that is a valid nodeset, then it is straightforward to find the corresponding length distribution and thus a code. We can find an optimal valid nodeset using the Coin Collector’s problem.

B. The Coin Collector’s Problem

Let \(2^Z\) denote the set of all integer powers of two. The Coin Collector’s problem of size \(m\) considers \(m\) “coins” with width \(\rho_i \in 2^Z\); one can think of width as coin face value, e.g., \(\rho_i = \frac{1}{4}\) for a quarter dollar (25 cents). Each coin also has weight \(\mu_i \in \mathbb{R}\). The final problem parameter is total width, denoted \(t\). The problem is then:

\[
\begin{align*}
\text{Minimize} & \quad \{B \subseteq \{1, \ldots, m\} \mid \sum_{i \in B} \mu_i \\ & \text{subject to} \quad \sum_{i \in B} \rho_i = t \}
\end{align*}
\]

(17)

We thus wish to choose coins with total width \(t\) such that their total weight is as small as possible. This problem is an input-restricted variant of the knapsack problem, which, in general, is NP-hard; no polynomial-time algorithms are known for such NP-hard problems [25], [26]. However, given sorted inputs, a linear-time solution to (17) was proposed in [14]. The algorithm in question is called the Package-Merge algorithm.

In the Appendix, we illustrate and prove a slightly simplified version of the Package-Merge algorithm. This algorithm allows us to solve the generalized quasiarithmetic convex coding problem (3). When we use this algorithm, we let \(I\) represent the \(m\) items along with their weights and widths. The optimal solution to the problem is a function of total width \(t\) and items \(I\). We denote this solution as \(CC(I, t)\) (read, “the [optimal] coin collection for \(I\) and \(t\)”). Note that, due to ties, this need not be unique, but we assume that one of the optimal solutions is chosen; at the end of Subsection IV-D we discuss which of the optimal solutions is best to choose.

C. A General Algorithm

We now formalize the reduction from the generalized quasiarithmetic convex coding problem to the Coin Collector’s problem.

We assert that any optimal solution \(N\) of the Coin Collector’s problem for \(t = n - 1\) on coins \(I = I\) is a nodeset for an optimal solution of the coding problem. This yields a suitable method for solving generalized quasiarithmetic convex penalties.

To show this reduction, first define \(\rho(N)\) for any \(N = \eta(l)\):

\[
\rho(N) \triangleq \sum_{(i, l) \in N} \rho(i, l) = \sum_{i=1}^{n} l_i 2^{-l} = \sum_{i=1}^{n} (1 - 2^{-l_i}) = n - \sum_{i=1}^{n} 2^{-l_i} = n - \kappa(l)
\]

Because the Kraft inequality is \(\kappa(l) \leq 1\), \(\rho(N)\) must
lie in \([n - 1, n)\) for prefix codes. The Kraft inequality is satisfied with equality at the left end of this interval. Optimal binary codes have this equality satisfied, since a strict inequality implies that the longest codeword length can be shortened by one, strictly decreasing the penalty without violating the inequality. Thus the optimal solution has \(\rho(N) = n - 1\).

Note that

\[
\mu(N) = \sum_{(i,l) \in N} \mu(i,l) = \sum_{i=1}^{n} \sum_{l=1}^{n} \mu(i,l) = \sum_{i=1}^{n} f(l_i, p_i) - \sum_{i=1}^{n} f(0, p_i) = \tilde{L}(p, l, f) - L_0(p, f).
\]

\(L_0(p, f)\) is a constant given fixed penalty and probability distribution. Thus, if the optimal nodeset corresponds to a valid code, solving the Coin Collector’s problem solves this coding problem. To prove the reduction, we need to prove that the optimal nodeset indeed corresponds to a valid code. We begin with the following lemma:

**Lemma 1:** Suppose that \(N\) is a nodeset of width \(x2^{-k} + r\) where \(k\) and \(x\) are integers and \(0 < r < 2^{-k}\). Then \(N\) has a subset \(R\) with width \(r\).

**Proof:** We use induction on the cardinality of the set. The base case \(|N| = 1\) is trivial since then \(x = 0\).
Assume the lemma holds for all $|N| < n$, and suppose $|\bar{N}| = n$. Let $\rho^* = \min_{j \in \bar{N}} \rho_j$ and $j^* = \arg \min_{j \in \bar{N}} \rho_j$. We can see $\rho^*$ as the smallest contribution to the width of $\bar{N}$ and $r$ as the portion of the binary expansion of the width of $\bar{N}$ to the right of $2^{-k}$. Then clearly $r$ must be an integer multiple of $\rho^*$. If $r = \rho^*$, $R = \{j^*\}$ is a solution. Otherwise let $N' = \bar{N}\setminus\{j^*\}$ (so $|N'| = n - 1$) and let $R'$ be the subset obtained from solving the lemma for set $N'$ of width $r - \rho^*$. Then $R = R' \cup \{j^*\}$.

We are now able to prove the main theorem:

**Theorem 4:** Any $N$ that is a solution of the Coin Collector’s problem for $t = \rho(N) = n - 1$ has a corresponding $t^N$ such that $N = \eta(I^N)$ and $\mu(N) = \min I(p, l, f) - L_0(p, f)$.

**Proof:** By monotonicity of the penalty function, any optimal solution satisfies the Kraft inequality with equality. Thus all optimal length distribution nodesets have $\rho(\eta(I)) = n - 1$. Since $N$ is a solution to the Coin Collector’s problem but is not a valid nodeset of a length distribution, then there exists an $(i, l)$ with $l > 1$ such that $(i, l) \in N$ and $(i, l - 1) \in I \setminus N$. Let $R' = N \cup \{(i, l - 1)\}\setminus\{(i, l)\}$, and thus $\rho(R') = n - 1 + 2^{-l}$ and, due to convexity, $\mu(R') \leq \mu(N)$. Thus, using Lemma 5 with $k = 0$, $x = n - 1$, and $r = 2^{-l}$, there exists an $R \subset R'$ such that $\rho(R) = 2^{-l}$ and $\mu(R \setminus R) < \mu(R') \leq \mu(N)$. Since we assumed $N$ to be an optimal solution of the Coin Collector’s problem, this is a contradiction, and thus any optimal solution of the Coin Collector’s problem corresponds to an optimal length distribution. 

Because the Coin Collector’s problem is linear in time and space, the overall algorithm finds an optimal code in $O(n l_{\max})$ time and space for any “well-behaved” $f(l_i, p_i)$, that is, any $f$ of the form specified for which same-width inputs would automatically be presorted by weight for the Coin Collector’s problem.

The complexity of the algorithm in terms of $n$ alone depends on the structure of both $f$ and $p$, because, if we can upper-bound the maximum length codeword, we can run the Package-Merge algorithm with fewer input nodes. In addition, if $f$ is not “well-behaved,” input to the Package-Merge algorithm might need to be sorted.

To quantify these behaviors, we introduce one definition and recall another:

**Definition 7:** A (coding) problem space is called a flat class if there exists a constant upper bound $u$ such that $\frac{\max_{l}}{\log_{2}{n}} < u$ for any solution $l$.

For example, the space of linear Huffman coding problems with all $p_i \geq \frac{1}{2n}$ is a flat class. (This may be shown using [23].)

Recall Definition 4 given in Section 1. A cost function $f(l, p)$ and its associated penalty $\tilde{L}$ are differentially monotonic or d.m. if, for every $l > 0$, whenever $f(l - 1, p_i)$ is finite and $p_i > p_j$, $f(l, p_i) - f(l - 1, p_i) > f(l, p_j) - f(l - 1, p_j)$. This implies that $f$ is continuous in $p$ at all but a countable number of points. Without loss of generality, we consider only cases in which it is continuous everywhere.

If $f(l, p)$ is differentially monotonic, then there is no need to sort the input nodes for the algorithm. Otherwise, sorting occurs on $l_{\max}$ rows with $O(n \log n)$ on each row, $O(n l_{\max} \log n)$ total. Also, if the problem space is a flat class, $l_{\max}$ is $O(\log n)$; it is $O(n)$ in general. Thus time complexity for this solution ranges from $O(n \log n)$ to $O(n^2 \log n)$ with space requirement $O(n \log n)$ to $O(n^2)$; see Table II for details. As indicated in the
time space
flat, d.m. \(O(n \log n)\) \(O(n \log n)\)
space-optimized \(O(n \log n)\) \(O(n)\)
not flat, d.m. \(O(n^2)\) \(O(n^2)\)
space-optimized \(O(n^2)\) \(O(n)\)
flat, not d.m. \(O(n \log^2 n)\) \(O(n \log n)\)
not flat, not d.m. \(O(n^2 \log n)\) \(O(n^2)\)

| problem type       | time            | space            |
|--------------------|-----------------|------------------|
| flat, d.m.         | \(O(n \log n)\) | \(O(n \log n)\) |
| space-optimized     | \(O(n \log n)\) | \(O(n)\)         |
| not flat, d.m.     | \(O(n^2)\)      | \(O(n^2)\)      |
| space-optimized     | \(O(n^2)\)      | \(O(n)\)         |
| flat, not d.m.     | \(O(n \log^2 n)\) | \(O(n \log n)\) |
| not flat, not d.m. | \(O(n^2 \log n)\) | \(O(n^2)\)      |

**TABLE I**

**COMPLEXITY FOR VARIOUS TYPES OF INPUTS**

(D. M. = DIFFERENTIALLY MONOTONIC)

Note that the length distribution returned by the algorithm need not have the property that \(l_i \leq l_j\) whenever \(i < j\). For example, if \(p_i = p_j\), we are guaranteed no particular inequality relation between \(l_i\) and \(l_j\) since we did not specify a method for breaking ties. Also, even if all \(p_i\) were distinct, there are cost functions for which we would expect the inequality relation reversed from the linear case. An example of this is \(f(l_i, p_i) = p_i^{-1}2^{l_i}\), although this represents no practical problem that the author is aware of.

Practical cost functions will, given a probability distribution for nonincreasing \(p_i\), generally have at least one optimal code of monotonically nondecreasing length. Differentially monotonicity is a sufficient condition for this, and we can improve upon the algorithm by insisting that the problem be differentially monotonic and all entries \(p_i\) in \(p\) be distinct; the latter condition we later relax. The resulting algorithm uses only linear space and quadratic time. First we need a definition:

**Definition 8:** A monotonic nodeset, \(N\), is one with the following properties:

\[(i, l) \in N \Rightarrow (i + 1, l) \in N \quad \text{for} \quad i < n \quad (18)\]

\[(i, l) \in N \Rightarrow (i, l - 1) \in N \quad \text{for} \quad l > 1 \quad (19)\]

This definition is equivalent to that given in [14].

An example of a monotonic nodeset is the set of nodes enclosed by the dashed line in Fig. 2. Note that a nodeset is monotonic only if it corresponds to a length distribution \(l\) with lengths sorted in nondecreasing order.

**Lemma 2:** If a problem is differentially monotonic and monotonically increasing and convex in each \(l_i\), and if \(p\) has no repeated values, then any optimal solution \(N = CC(I, n - 1)\) is monotonic.

**Proof:** The second monotonic property (19) was proved for optimal nodesets in Theorem 4 and the first is now proved with a simple exchange argument, as in [27, pp. 97–98]. Suppose we have optimal \(N\) that violates the first property (18). Then there exist unequal \(i\) and \(j\) such that \(p_i < p_j\) and \(l_i < l_j\) for optimal codeword lengths \(l\) \((N = \eta(l))\). Consider \(l'\) with lengths for symbols \(i\) and \(j\) interchanged. Then

\[\tilde{L}(p, l', f) - \tilde{L}(p, l, f) = \sum_k f(l'_k, p_k) - \sum_k f(l_k, p_k) = (f(l_j, p_j) - f(l_i, p_i)) - (f(l_i, p_i) - f(l_i, p_i)) = \sum_{l_{i \rightarrow j}} (M_f(l, p_j) - M_f(l, p_i)) < 0\]

where we recall that \(M_f(l, p) \triangleq f(l, p) - f(l - 1, p)\) and the final inequality is due to differential monotonicity. However, this implies that \(l\) is not an optimal code, and thus we cannot have an optimal nodeset without monotonicity unless values in \(p\) are repeated.

Taking advantage of this relation to trade off a constant factor of time for drastically reduced space complexity has been done in [6] for the case of the length-limited (linear) penalty [5]. We now extend this to all convex differentially monotonic cases.
Note that the total width of items that are each less than or equal to width \( \rho \) is less than \( 2n \rho \). Thus, when we are processing items and packages of width \( \rho \), fewer than \( 2n \) packages are kept in memory. The key idea in reducing space complexity is to keep only four attributes of each package in memory instead of the full contents. In this manner, we use linear space while retaining enough information to reconstruct the optimal nodeset in algorithmic postprocessing.

Define \( n_{\text{mid}} \triangleq \lceil \frac{1}{2} (n_{\text{max}}+1) \rceil \). Package attributes allow us to divide the problem into two subproblems with total complexity that is at most half that of the original problem. For each package \( S \), we retain the following attributes:

1) Weight: \( \mu(S) \triangleq \sum_{(i,l) \in S} \rho(i,l) \)
2) Width: \( \rho(S) \triangleq \sum_{(i,l) \in S} \rho(i,l) \)
3) Midct: \( \nu(S) \triangleq |S \cap I_{\text{mid}}| \)
4) Hiwidth: \( \psi(S) \triangleq \sum_{(i,l) \in S \cap I_{\text{hi}}} \rho(i,l) \)

where \( I_{\text{hi}} \triangleq \{(i,l) \mid l > l_{\text{mid}}\} \) and \( I_{\text{mid}} \triangleq \{(i,l) \mid l = l_{\text{mid}}\} \). We also define \( I_{\text{lo}} \triangleq \{(i,l) \mid l < l_{\text{mid}}\} \).

This retains enough information to complete the “first run” of the algorithm with \( O(n) \) space. The result will be the package attributes for the optimal nodeset \( N \). Thus, at the end of this first run, we know the value for \( m = \nu(N) \), and we can consider \( N \) as the disjoint union of four sets, shown in Fig. 2.

1) \( A = \) nodes in \( N \cap I_{\text{lo}} \) with indices in \([1, n-m]\),
2) \( B = \) nodes in \( N \cap I_{\text{lo}} \) with indices in \([n-m+1, n]\),
3) \( C = \) nodes in \( N \cap I_{\text{mid}} \).
4) \( D = \) nodes in \( N \cap I_{\text{hi}} \).

Due to monotonicity of \( N \), it is trivial that \( C = [n-m+1,n] \times \{l_{\text{mid}}\} \) and \( B = [n-m+1,n] \times [1,l_{\text{mid}}-1] \).

Note then that \( \rho(C) = m2^{-l_{\text{mid}}} \) and \( \rho(B) = m[1 - 2^{-(l_{\text{mid}}-1)}] \). Thus we need merely to recompute which nodes are in \( A \) and in \( D \).

Because \( D \) is a subset of \( I_{\text{hi}} \), \( \rho(D) = \psi(N) \) and \( \rho(A) = \rho(N) - \rho(B) - \rho(C) - \rho(D) \). Given their respective widths, \( A \) is a minimal weight subset of \([1, n-m] \times [1,l_{\text{mid}}-1] \) and \( D \) is a minimal weight subset of \([n-m+1,n] \times [l_{\text{mid}}+1,l_{\text{max}}] \). The nodes at each level of \( A \) and \( D \) may be found by recursive calls to the algorithm. In doing so, we use only \( O(n) \) space. Time complexity, however, remains the same; we replace one run of an algorithm on \( n_{\text{max}} \) nodes with a series of runs, first one on \( n_{\text{max}} \) nodes, then two on an average of at most \( \frac{1}{4}n_{\text{max}} \) nodes each, then four on \( \frac{1}{16}n_{\text{max}} \), and so forth. Formalizing this analysis:

**Theorem 5:** The above recursive algorithm for generalized quasiarithmetic convex coding has \( O(n_{\text{max}}) \) time complexity. [14]

**Proof:** As indicated, this recurrence relation is considered and proved in [14, pp. 472–473], but we analyze it here for completeness. To find the time complexity, set up the following recurrence relation: Let \( T(n,l) \) be the worst case time to find the minimal weight subset of \([1,n] \times [1,l] \) (of a given width), assuming the subset is monotonic. Then there exist constants \( c_1 \) and \( c_2 \) such that, if we define \( \hat{l} \triangleq l_{\text{mid}} - 1 \leq \lfloor \frac{l}{2} \rfloor \) and \( \hat{\hat{l}} \triangleq l - \hat{l} - 1 \leq \lfloor \frac{l}{4} \rfloor \), and we let an adversary choose the corresponding \( \hat{n} + \hat{\hat{n}} = n \),

\[
T(n,l) \leq c_1 n \quad \text{for } l < 3 \\
T(n,l) \leq c_2 n l + T(\hat{n},\hat{l}) + T(\hat{n},\hat{l}) \quad \text{for } l \geq 3,
\]

where \( l < 3 \) is the base case. Then \( T(n,l) = O(\tau(n,l)) \), where \( \tau \) is any function satisfying the recurrence

\[
\tau(n,l) \geq c_1 n \quad \text{for } l < 3 \\
\tau(n,l) \geq c_2 n l + \tau(\hat{n},\hat{l}) + \tau(n-\hat{n},\hat{l}) \quad \text{for } l \geq 3,
\]

which \( \tau(n,l) = (c_1 + 2c_2)n l \) does. Thus, the time complexity is \( O(n_{\text{max}}) \).

The overall complexity is \( O(n) \) space and \( O(n_{\text{max}}) \) time — \( O(n \log n) \) considering only flat classes, \( O(n^2) \).
in general, as in Table I.

However, the assumption of distinct \( p_i \)'s puts an undesirable restriction on our input. In their original algorithm from [14], Larmore and Hirschberg suggest modifying the probabilities slightly to make them distinct, but this is unnecessarily inelegant, as the resulting algorithm has the drawbacks of possibly being slightly nonoptimal and being nondeterministic; that is, different implementations of the algorithm could result in the same input yielding different outputs. A deterministic variant of this approach could involve modifications by multiples of a suitably small variable \( \epsilon > 0 \) to make identical values distinct.

In [28], another method of tie-breaking is presented for alphabetic length-limited codes. Here, we present a simpler alternative analogous to this approach, one which is both deterministic and applicable to all differentially monotonic instances.

Recall that \( p \) is a nonincreasing vector. Thus items of a given width are sorted for use in the Package-Merge algorithm; use this order for ties. For example, if we use the nodes in Fig. I — \( n = 4 \), \( f(l, p) = pl^2 \) — with probability \( p = (0.5, 0.2, 0.2, 0.1) \), then nodes (4, 3) and (3, 3) are the first to be paired, the tie between (2, 3) and (3, 3) broken by order. Thus, at any step, all identical-width items in one package have adjacent indices. Recall that packages of items will be either in the final nodeset or absent from it as a whole. This scheme then prevents any of the nonmonotonicity that identical \( p_i \)'s might bring about.

In order to ensure that the algorithm is fully deterministic — whether or not the linear-space version is used — the manner in which packages and single items are merged must also be taken into account. We choose to merge nonmerged items before merged items in the case of ties, in a similar manner to the two-queue bottom-merge method of Huffman coding [20], [29]. Thus, in our example, the node (1, 2) is chosen whereas the package of items (4, 3) and (3, 3) is not. This leads to the optimal length vector \( l = (2, 2, 2, 2) \), rather than \( l = (1, 2, 3, 3) \) or \( l = (1, 3, 2, 3) \), which are also optimal. As in bottom-merge Huffman coding, the code with the minimum reverse lexicographical order among optimal codes is the one produced. This is also the case if we use the position of the “last” node in a package (in terms of the value of \( nl + i \)) in order to choose those with lower values, as in [28]. However, the above approach, which is easily

![Fig. 2. The set of nodes \( I \), an optimal nodeset \( N \), and disjoint subsets \( A, B, C, D \)]
shown to be equivalent via induction, eliminates the need for keeping track of the maximum value of \( nl + i \) for each package.

**E. Further Refinements**

In this case using a bottom-merge-like coding method has an additional benefit: We no longer need assume that all \( p_i \neq 0 \) to assure that the nodeset is a valid code. In finding optimal binary codes, of course, it is best to ignore an item with \( p_i = 0 \). However, consider nonbinary output alphabets, that is, \( D > 2 \). As in Huffman coding for such alphabets, we must add “dummy” values of \( p_i = 0 \) to assure that the optimal code has the Kraft inequality satisfied with equality, an assumption underlying both the Huffman algorithm and ours. The number of dummy values needed is \( \text{mod}(D - n, D - 1) \) where \( \text{mod}(x, y) \triangleq x - y \lfloor \frac{x}{y} \rfloor \) and where the dummy values each consist of \( l_{\text{max}} \) nodes, each node with the proper width and with weight \( 0 \). With this preprocessing step, finding an optimal code should proceed similarly to the binary case, with adjustments made for both the Package-Merge algorithm and the overall coding algorithm due to the formulation of the Kraft inequality and maximum length. A complete algorithm is available, with proof of correctness, in [21].

Note that we have assumed for all variations of this algorithm that we knew a maximum bound for length, although in the overall complexity analysis for binary coding we assumed this was \( n - 1 \) (except for flat classes). We now explore a method for finding better upper bounds and thus a more efficient algorithm. First we present a definition due to Larmore:

**Definition 9:** Consider penalty functions \( f \) and \( g \). We say that \( g \) is flatter than \( f \) if, for probabilities \( p \) and \( p' \) and positive integers \( l \) and \( l' \) where \( l' > l \), \( M_g(l, p)M_f(l', p') \leq M_f(l, p)M_g(l', p') \) (where, again, \( M_f(l, p) \triangleq f(l, p) - f(l - 1, p) \) [6].

A consequence of the Convex Hull Theorem of [6] is that, given \( g \) flatter than \( f \), for any \( p \), there exist \( f \)-optimal \( l^{(f)} \) and \( g \)-optimal \( l^{(g)} \) such that \( l^{(f)} \) is greater lexicographically than \( l^{(g)} \) (again, with lengths sorted largest to smallest). This explains why the word “flatter” is used.

Thus, for penalties flatter than the linear penalty, we can obtain a useful upper bound, reducing complexity. All convex quasiarithmetic penalties are flatter than the linear penalty. (There are some generalized quasiarithmetic convex coding penalties that are not flatter than the linear penalty — e.g., \( f(l_i, p_i) = l_i p_i^2 \) — and some flatter penalties that are not Campbell/quasiarithmetic — e.g., \( f(l_i, p_i) = 2 l_i (p_i + 0.1 \sin \pi p_i) \) — so no other similarly straightforward relation exists.) For most penalties we have considered, then, we can use the upper bounds in [23] or the results of a pre-algorithmic Huffman coding of the symbols to find an upper bound on codeword length.

A problem in which pre-algorithmic Huffman coding would be useful is delay coding, in which the quadratic penalty \( \Phi \) is solved for \( O(n^2) \) values of \( \alpha \) and \( \beta \) [6]. In this application, only one traditional Huffman coding would be necessary to find an upper bound for all quadratic cases.

With other problems, we might wish to instead use a mathematically derived upper bound. Using the maximum unary codeword length of \( n - 1 \) and techniques involving the Golden Mean, \( \Phi \triangleq \frac{\sqrt{5} + 1}{2} \), Buro in [23] gives the upper limit of length for a (standard) binary Huffman codeword as

\[
\min \left\{ \left[ \left\lfloor \log_\Phi \left( \frac{\Phi + 1}{p_n \Phi + p_{n-1}} \right) \right\rfloor \right] \cdot n - 1 \right\}
\]

which would thus be an upper limit on codeword length for the minimal optimal code obtained using any flatter
penalty function, such as a convex quasiarithmetic function. This may be used to reduce complexity, especially in a case in which we encounter a flat class of problem inputs.

In addition to this, one can improve this algorithm by adapting the binary length-limited Huffman coding techniques of Moffat (with others) in [30]–[34]. We do not explore these, however, as these cannot improve asymptotic results with the exception of a few special cases. Other approaches to length-limited Huffman coding with improved algorithmic complexity [35], [36] are not suited for extension to nonlinear penalties.

V. CONCLUSION

With a similar approach to that taken by Shannon for Shannon entropy and Campbell for Rényi entropy, one can show redundancy bounds and related properties for optimal codes using Campbell’s quasiarithmetic penalties and generalized entropies. For convex quasiarithmetic costs, building upon and refining Larmore and Hirschberg’s methods, one can construct efficient algorithms for finding an optimal code. Such algorithms can be readily extended to the generalized quasiarithmetic convex class of penalties, as well as to the delay penalty, the latter of which results in more quickly finding an optimal code for delay channels.

One might ask whether the aforementioned properties can be extended; for example, can improved redundancy bounds similar to [37]–[40] be found? It is an intriguing question, albeit one that seems rather difficult to answer given that such general penalties lack a Huffman coding tree structure. In addition, although we know that optimal codes for infinite alphabets exist given the aforementioned conditions, we do not know how to find them. This, as with many infinite alphabet coding problems, remains open.

It would also be interesting if the algorithms could be extended to other penalties, especially since complex models of queueing can lead to other penalties aside from the delay penalty mentioned here. Also, note that the monotonicity property of the examples we consider implies that the resulting optimal code can be alphabetic, that is, lexicographically ordered by item number. If we desire items to be in a lexicographical order different from that of probability, however, the alphabetic and nonalphabetic cases can have different solutions. This was discussed for the length-limited penalty in [28]; it might be of interest to generalize it to other penalties using similar techniques and to prove properties of alphabetic codes for such penalties.

ACKNOWLEDGMENTS

The author wishes to thank Thomas Cover, John Gill, and Andrew Brzezinski for feedback on this paper and research, as well as the anonymous reviewers for their numerous suggestions for improvement. Discussions and comments from the Stanford Information Theory Group and Benjamin Van Roy are also greatly appreciated, as is encouragement from Brian Marcus.

APPENDIX

THE PACKAGE-MERGE ALGORITHM

Here we illustrate and prove the correctness of a recursive version of Package-Merge algorithm for solving the Coin Collector’s problem. This algorithm was first presented in [14], which also has a linear-time iterative implementation.
Restating the Coin Collector’s problem:

\[
\begin{align*}
\text{Minimize} & \quad \{B \subseteq \{1, \ldots, m\}\} \quad \sum_{i \in B} \mu_i \\
\text{subject to} & \quad \sum_{i \in B} \rho_i = t \\
\text{where} & \quad m \in \mathbb{Z}_+ \\
& \quad \mu_i \in \mathbb{R} \\
& \quad \rho_i \in 2\mathbb{Z} \\
& \quad t \in \mathbb{R}_+ \\
\end{align*}
\]  

(20)

In our notation, we use \(i \in \{1, \ldots, m\}\) to denote both the index of a coin and the coin itself, and \(I\) to represent the \(m\) items along with their weights \(\{\mu_i\}\) and widths \(\{\rho_i\}\). The optimal solution, a function of total width \(t\) and items \(I\), is denoted \(\text{CC}(I, t)\).

Note that we assume the solution exists but might not be unique. In the case of distinct solutions, tie resolution for minimizing arguments may for now be arbitrary or rule-based; we clarify this in Subsection IV-D. A modified version of the algorithm considers the case where a solution might not exist, but this is not needed here. Because a solution exists, assuming \(t > 0\), \(t = \omega t_{\text{pow}}\) for some unique odd \(\omega \in \mathbb{Z}\) and \(t_{\text{pow}} \in 2\mathbb{Z}\). (Note that \(t_{\text{pow}}\) need not be an integer. If \(t = 0\), \(\omega\) and \(t_{\text{pow}}\) are not defined.)

Algorithm variables

At any point in the algorithm, given nontrivial \(I\) and \(t\), we use the following definitions:

**Remainder**

\[t_{\text{pow}} \triangleq \text{the unique } x \in 2\mathbb{Z}\text{ such that } \frac{t}{x}\text{ is an odd integer}\]

**Minimum width**

\[\rho^* \triangleq \min_{i \in I} \rho_i \text{ (note } \rho^* \in 2\mathbb{Z})\]

**Small width set**

\[I^* \triangleq \{i \mid \rho_i = \rho^*\}\] (by definition, \(|I^*| \geq 1\)

“First” item

\[i^* \triangleq \arg \min_{i \in I^*} \mu_i\]

“Second” item

\[i^{**} \triangleq \arg \min_{i \in I \setminus \{i^*\}} \mu_i\] (or null \(\Lambda\) if \(|I^*| = 1\)

Then the following is a recursive description of the algorithm:

**Recursive Package-Merge Procedure** [14]

**Basis.** \(t = 0\): \(\text{CC}(I, t)\) is the empty set.

**Case 1.** \(\rho^* = t_{\text{pow}}\) and \(I \neq \emptyset\): \(\text{CC}(I, t) = \text{CC}(I \setminus \{i^*\}, t - \rho^*) \cup \{i^*\}\).

**Case 2a.** \(\rho^* < t_{\text{pow}}, I \neq \emptyset, \text{ and } |I^*| = 1\): Create \(i',\) a new item with weight \(\mu_{i'} = \mu_{i^*} + \mu_{i^{**}}\) and width \(\rho_{i'} = \rho_{i^*} + \rho_{i^{**}} = 2\rho^*\). This new item is thus a combined item, or package, formed by combining items \(i^*\) and \(i^{**}\). Let \(S' = \text{CC}(I \setminus \{i^*, i^{**}\} \cup \{i'\}, t)\) (the optimization of the packaged version). If \(i' \in S'\), then \(\text{CC}(I, t) = S' \setminus \{i'\} \cup \{i^*, i^{**}\}\); otherwise, \(\text{CC}(I, t) = S'\).

**Theorem 6:** If an optimal solution to the Coin Collector’s problem exists, the above recursive (Package-Merge) algorithm will terminate with an optimal solution.

**Proof:** We show that the Package-Merge algorithm produces an optimal solution via induction on the depth
Fig. 3. A simple example of the Package-Merge algorithm

do the recursion. The basis is trivially correct, and each inductive case reduces the number of items by one. The inductive hypothesis on $t \geq 0$ and $\mathcal{I} \neq \emptyset$ is that the algorithm is correct for any problem instance that requires fewer recursive calls than instance $(\mathcal{I}, t)$.

If $\mathcal{I} = \emptyset$ and $t \neq 0$, or if $\rho^* > t_{\text{pow}} > 0$, then there is no solution to the problem, contrary to our assumption. Thus all feasible cases are covered by those given in the procedure. Case 1 indicates that the solution must contain an odd number of elements of width $\rho^*$. These must include the minimum weight item in $\mathcal{I}^*$, since otherwise we could substitute one of the items with this "first" item and achieve improvement. Case 2 indicates that the solution must contain an even number of elements of width $\rho^*$. If this number is 0, neither $i^*$ nor $i^{**}$ is in the solution. If it is not, then they both are. If $i^{**} = \Lambda$, the number is 0, and we have Case 2a. If not, we may "package" the items, considering the replaced package as one item, as in Case 2b. Thus the inductive hypothesis holds and the algorithm is correct.

Fig. 3 presents a simple example of this algorithm at work, finding minimum total weight items of total width $t = 3$ (or, in binary, $11_2$). In the figure, item width represents numeric width and item area represents numeric weight. Initially, as shown in the top row, the minimum weight item with width $\rho_{i^*} = t_{\text{pow}} = 1$ is put into the solution set. Then, the remaining minimum width items are packaged into a merged item of width $2$ ($10_2$). Finally, the minimum weight item/package with width $\rho_{i^{**}} = t_{\text{pow}} = 2$ is added to complete the solution.
set, which is now of weight 6. The remaining packaged item is left out in this case; when the algorithm is used for coding, several items are usually left out of the optimal set.
