Abstract
We use a two-level energy model to understand the conversion process that takes place in thermoradiative cells and to compare it with the conversion process that happens in photovoltaic cells. In this way, we show that in both kinds of converters the conversion process can be studied as the succession of a change in the populations of the levels that occur at constant chemical potential and a change in the value of the chemical potential of the two levels that happens while keeping their populations constant. As an application of the model, we will discuss why in thermoradiative cells the open-circuit voltage is negative while it is positive in photovoltaic cells. We also show that the expression for the open-circuit voltage is the same in both kinds of cells but that due to the values of the temperatures it is negative in thermoradiative cells and positive in photovoltaic ones.

1 Introduction
Thermoradiative cells (TRCs) and photovoltaic cells (PVCs) [1, 2] are two different devices that generate power using the radiative energy transfer between reservoirs that are kept at constant temperatures. Both TRCs and PVCs are made using semiconductors, and they work in a very similar way. The main difference in their working mode is that while TRCs work at high temperature and exchange photons with a very low temperature environment, PVCs stay at room temperature and receive photons from a very hot source (the Sun).

TRCs are, somehow, a much more new concept than PVCs. Very recently, Strandberg analyzed the performance of far-field TRCs [3] and Samthanam and Fan [4] proved experimentally their working principles. In this last work, it was found that TRCs work with an efficiency much lower than the one predicted in Strandberg’s work. In order to improve the performance of TRCs, some authors [5–8] considered the possibility of placing a heat sink between the TRC and its environment. This idea derived from the concept of thermophotovoltaic devices showed that it is possible to improve the performance of TRCs. In fact in thermophotovoltaic cells, using the impedance matching condition [7] and by means of a common design for the PVC absorbed and the hot emitter that emits photons toward the PVC, it is possible to maximize the heat transfer between those two parts of the cell and, consequently, to maximize the cell output power [6–10]. The same can be done in TRCs where it is necessary to have a common design of the cell emitter and the cold sink that receives the photons emitter from the hot cell [6, 8].

In this work we study some fundamental issues of thermoradiative energy conversion. To do it, we present a simple description of the thermoradiative energy conversion using simple reasonings of statistical physics. Simple models in physics are very interesting to understand some of the fundamental properties of physical systems and to achieve knowledge about them. Following this thinking, we believe that it is always of interest to have easy-to-follow articles that allow to understand the principles of physical processes. In the past years, this way of thinking was applied for the understanding of the photovoltaic energy conversion [11–15] with...
a great success and we think that it is interesting to apply it
to the understanding of new energy conversion techniques
such as the thermoradiative energy conversion.

In order to properly present the characteristics of thermo-
radiative energy conversion, we will simultaneously consider
those of photovoltaic conversion. In this way, the reader of
this work will be able to get a very clear idea of how these
two types of energy conversion are linked by a common
fundamental physical description. Thus, thermoradiative
and photovoltaic energy conversion can be understood as
counterparts of each other as it has already been claimed by
some authors [16–18]. Moreover, our exposition clarifies
the role that the Carnot factor has, in the description of the
thermoradiative energy conversion, a topic that has not been
treated in deep in the literature.

According to some previous works, a simple picture hav-
ing two steps

- Creation of an excitation by light absorption.
- Charge separation and a subsequent splitting of Fermi
  levels.

is enough to understand some of the fundamentals of pho-
tovoltaic conversion. Equally a simple picture of thermora-
diative conversion can be achieved assuming the two steps,

- Electron de-excitation and photon emission.
- Charge separation and a subsequent splitting of Fermi
  levels.

In both cases, and to simplify the reading of the article,
we will assume that the excitations/recombinations occur
between electrons and holes that exist in the conduction and
valence bands of a semiconductor.

It is important to note that both thermoradiative and
photovoltaic conversions are affected by other physical pro-
cesses besides those mentioned. Thus, TRCs do not only
emit photons but also absorb them as the temperature of
their surroundings is different to 0 K. Similarly, photovoltaic
cells (PVCs) are not at 0 K so they emit photons toward
their surroundings while working. In this work, for the sake
of simplicity, we will consider that these two processes
(absorptions in TRCs and emissions in PVCs) involve a very
small amount of photons and that their existence does not
affect considerably the statistical distribution of electrons in
the semiconductor.

As said, both TRCs and PVCs work interacting to an
external field of photons with a temperature $T_p$ that is dif-
ferent to the cell temperature $T_s$. In TRCs $T_p > T_s$ what
increases in them the number of recombinations to a value
that is greater than that of the equilibrium situation. Conse-
quently, in TRCs the lower (higher) energy levels have bigger
(smaller) populations than in equilibrium. In PVCs the
situation is the opposite. The cell now interacts with photons
with a temperature $T_p < T_s$. This interaction increases the
number of excitations in the system, so the population of
the energy levels of high (low) energy increases over (drops
below) the value of equilibrium.

Once we are in the situations described in the preceeding
paragraph, electronic currents are created in both TRCs and
PVCs. In TRCs hot electrons are injected in the conduc-
tion band thus creating an overpopulation. As this situation
happens having the cell connected to a cooler environment,
the cell tries to cool down. If we force the only way to lose
energy in the TRC is through radiative transitions, we will
get many electrons to de-excite radiatively to the valence
band. Once the electrons are in the valence band, charge sep-
aration occurs. In TRCs this process happens as the electrons
that have a big temperature diffuse toward the contact that
exist in the valence band. Consequently, an electrical current
circulates in the TRC that has opposite direction to that of
the current of PVCs. This process corresponds to the separa-
tion of charges, which, as we see in TRC cells, is somewhat
different from how it is in PVC cells. This is so because in
PVCs electrons are separated in the built-in electric field of
the junction that drives the electrons and holes to contacts
of opposite sign (electrons are driven to the cell n-side and
holes to the p-side), thus creating the electronic current.

As it was said in the proceeding paragraph, in both cases
exist electron separation in the pn-junction of the cell. A
simple picture of this is achieved considering that once
separated both electrons and holes are driven by the inter-
nal forces to different particle reservoirs. These two particle
reservoirs can be considered to be at the same temperature
but at different chemical potential [19]. It is that separation
of the chemical potential what gives the cell output voltage.
As we will see later, a fundamental difference between TRCs
and PVCs is that the chemical potential difference is nega-
tive in the first ones and positive in the second ones.

Our work is organized as follows. In Sect. 2 we present
a simple model of thermoradiative energy conversion.

2 Statistical model for thermoradiative
energy conversion

Our simple model for both TRCs and PVCs consists of
a two-electronic-level system with energies $E_1$ and $E_2$
with $E_1 > E_2$ that according to Fig. 1 exchange photons in
radiative processes. We assume that initially this system is in thermal equilibrium at the same temperature $T_1$ of its surroundings so there is no net exchange of photons between the cell and the surroundings. In this situation the population of the levels $E_1$ (population of electrons) and $E_2$ (population of holes) are
\begin{equation}
  p_i = \frac{1}{1 + s_i} \quad \text{with} \quad s_i = \exp \left[ \frac{E_i - \mu}{T_1} \right].
\end{equation}

Here $i = 1, 2$ denote the two levels of the system or electrons (1) and holes (2); $\mu$ is the electrochemical potential. As we are in an equilibrium situation, $\mu$ is the same for electrons and holes. The two probabilities $p_1$ and $p_2$ satisfy $p_1 + p_2 = 1$, so we know that $p_2 = 1 - p_1$. This equality can be used to write down $s_1 \times s_2 = 1$ what leads to
\begin{equation}
  E_1 + E_2 = 2\mu \rightarrow \mu = \frac{E_1 + E_2}{2}.
\end{equation}

Equation (2) shows that in equilibrium the chemical potential of the system is in the middle of the energy bandgap that separates the $E_1$ and $E_2$ levels. This equality that was deduced before for PVCs [19] is also valid for TRCs.

Let us now drive the cells out of equilibrium letting them to interact to their surroundings. For TRCs the interaction to the environment causes the de-excitation of photons from $E_1$ to $E_2$ and the emission of photons to the surroundings of the cell. PVCs cells are driven out of the equilibrium assuming that they absorb photons coming from a hot source such as the sun. This interaction causes that a part of the electrons that are in the level $E_2$ are excited to the level $E_1$.

In both cells the interaction to the external field causes a change in $p_1$ and $p_2$; that now take the values $p_1^*$ and $p_2^*$. Proceeding in analogy to the equilibrium situation, we assume
\begin{equation}
  p_i^* = \frac{1}{1 + s_i^*} \quad \text{with} \quad s_i^* = \exp \left[ \frac{E_i - \mu^*}{T_p} \right].
\end{equation}

Let us note that the two populations $p_1^*$ and $p_2^*$ are still given by the Fermi–Dirac distribution function but that now the distribution is characterized by the temperature $T_p$ of the photon field interacting with the cell. It is important to stress that for TRCs $T_p < T_1$ and for PVCs $T_p > T_1$. Although we know that $p_1^* \neq p_1$ and $p_2^* \neq p_2$, the two probabilities $p_1^*$ and $p_2^*$ still satisfy $p_1^* + p_2^* = 1$ what results in
\begin{equation}
  s_1^* \times s_2^* = 1 \quad \text{or} \quad E_1 + E_2 = \mu_1^* + \mu_2^*. 
\end{equation}

Considering that the interaction of the cell with the radiation of the photon field occurs long enough for the system to reach thermal equilibrium, we can assume that $\mu_1^* = \mu_2^*$ and therefore $\mu_1^* = \mu_2^* = \mu$. This means that the Fermi level that characterizes the system does not change when it interacts with external radiation. This result is true for both PVCs and TRCs.

However, the effect of connecting the two kind of cells to the external radiation is not the same. On the one hand, in TRCs the external field of photons is characterized by a temperature $T_p < T_1$ (let us think about the example given by Strandberg for the operation of TRCs where they exchange photons to the sky [3]) so the interaction leads to generate de-ex Citations in the cell. This reduces the population of the energy level $E_1$ while increases that of the energy level $E_2$. On the other hand, in PVCs that are connected to a hot photonic field, the temperature of the external radiation field is $T_p \approx T_{sun} = 5870$ K. As $T_p > T_1$ the interaction to the photon increases $p_1$ and reduces $p_2$, i.e., it induces excitations in the PVC.

To model the formation of electronic currents in both TRCs and PVCs, we will assume that each of the two levels of the system $E_1$ and $E_2$ is connected to a different particle reservoir. We will also consider that the two reservoirs are characterized by having the same temperature and that it coincides with $T_p$, the temperature of the photon field that interacts with the cell. Furthermore, we will assume that the two reservoirs are characterized by different chemical potentials. Thus, the chemical potentials are $\mu_1^*$ for the reservoir connected to the energy level $E_1$ and $\mu_2^*$ for the one connected to the energy level $E_2$. We also now consider that the formation of the electric current in the cell (it does not matter if it is thermoradiative or photovoltaic) occurs in such a way that the probabilities of occupation of the levels $E_1$ and $E_2$ are preserved. That is, during the functioning of the
cell, the populations \( p'_1 \) and \( p'_2 \) of the two levels are those that were determined by the interaction between the cell and the external field of photons. However, and as is common in works on solar cells, we will calculate \( p'_1 \) and \( p'_2 \) considering that the temperature characterizing the Fermi–Dirac distribution is \( T_s \). If this is done, we must also consider that the chemical potentials \( \mu'_1 \) and \( \mu'_2 \) are different from \( \mu_1 \) and \( \mu_2 \) and that in general \( \mu'_1 \neq \mu'_2 \). Doing this we also know that \( \mu'_1 (\mu'_2) \) is the unique chemical potential at the n-side (p-side) of the junction [19].

To calculate the values of the two chemical potentials \( \mu'_1 \) and \( \mu'_2 \), we use the condition of having constant populations in the levels \( E_1 \) and \( E_2 \). Thus, the conditions \( p'_1 = p'_1^s \) and \( p'_2 = p'_2^s \) stand. From them we obtain,

\[
\mu'_1 = \frac{T_s}{T_p} \mu + E_1 \left( 1 - \frac{T_s}{T_p} \right) \tag{5}
\]

and

\[
\mu'_2 = \frac{T_s}{T_p} \mu + E_2 \left( 1 - \frac{T_s}{T_p} \right) \tag{6}
\]

These two conditions are the same for TRCs and for PVCs. However, they have different implications since in TRCs \( T_p < T_s \) and in PVCs \( T_p > T_s \). For PVCs we have \( T_s/T_p < 1 \), so the factor within the brackets appearing in (5) and (6) has the form of the Carnot efficiency of a reversible heat engine working between two heat reservoirs at \( T_p \) and \( T_s \). However, in TRCs we have \( T_s/T_p > 1 \) so \( \left( 1 - \frac{T_s}{T_p} \right) < 0 \) is not a Carnot factor.

Doing now the difference \( \mu'_1 - \mu'_2 \), we obtain,

\[
qV_{voc} = \mu'_1 - \mu'_2 = (E_1 - E_2) \left( 1 - \frac{T_s}{T_p} \right) \tag{7}
\]

This equation shows that the cell open-circuit voltage \( V_{voc} = (\mu'_1 - \mu'_2)/q \) is smaller in TRCs than in PVCs. Moreover, in TRCs we have \( V_{voc} < 0 \).

Finally, we present in Fig. 2 two thermodynamic diagrams of the populations of the energy levels \( E_1 \) and \( E_2 \) in TRCs (a) and PVCs (b) in terms of the chemical potential \( \mu \). In the two panels of the figure, we represent in black the population of the level \( E_1 \) and in red that of the level \( E_2 \). We use continuous lines for the populations when the system is in equilibrium and dashed ones when it is in contact to the external radiation. According to Fig. 2, the conversion happening in both TRCs and PVCs can be understood as the combination of an isochemical process (process marked as \( a \) in the two panels of the figure) where the population of the level of bigger energy \( E_1 \) reduces in TRCs and increases in PVCs while the chemical potential is kept constant. We also mark process \( b \) (that corresponds to the change separation) in which the populations of the two energy levels remains constant while their chemical potentials change. In TRCs the chemical potential \( \mu'_1 \) of the level \( E_1 \) is at a lower energy (it moves to the left in the figure) than it was in the system at the initial equilibrium temperature \( T_s \). At the same time, in TRCs the chemical potential \( \mu'_2 \) associated to \( E_2 \) also changes; it moves toward bigger energies (it moves to the right in Fig. 2). Thus, in the final (working situation) of TRCs we have \( \mu'_2 > \mu'_1 \) and \( qV_{voc} < 0 \). This behavior is opposite to the one found in PVCs where \( \mu'_1 \) moves toward higher energies, \( \mu'_2 \) toward lower ones and \( qV_{voc} > 0 \).

3 Conclusions

In this work we used a simple statistical model of two energy levels to understand some basic features of thermoradiative energy conversion. In order to properly establish the context
of our presentation and to demonstrate that the operation of thermoradiative cells is similar to that of photovoltaic cells, we have presented our discussion comparing the processes that occur in the two kind of cells. Our analysis has led us to see the similarities and differences that exist between photovoltaic and thermoradiative cells.

Thus, we have understood that in thermoradiative cells, as in photovoltaic ones, the energy conversion can be viewed as a two-step process. In the first step the populations of the two levels change. The change happens keeping the chemical potential of the two levels constant. In thermoradiative cells this step represents the part of the conversion where electrons de-excite from the upper energy levels to the lower energy ones. The process entails an increase of the population of the levels of lower energy and a reduction of the population of those of higher energy. In photovoltaic cells the first step represents the process where electrons excite from the lower energy levels to the higher ones. Thus, the population of the lower energy levels decreases and that of the bigger energy increases. As we see, the interaction to the external field causes opposite effects on the populations of the energy levels of TRCs and PVCs.

In the process of charge separation, and in both kinds of cells, the chemical potentials associated to the high and low energy levels change. In thermoradiative cells the chemical potential of the energy levels with the lower energy increases and that of the energy levels with the higher energy decreases. In normal working situations of thermoradiative cells, the chemical potential of the high energy level is smaller than the one of the other levels. Thus, in TRCs it is said that the difference of the chemical potentials is negative and so it is the cell open-circuit voltage. This situation is the opposite to that found in PVCs where the difference between the two chemical potentials is positive and so it is the cell open-circuit voltage.
