Abstract
Volitionality and subject animacy are fundamental and closely related properties of an event. Their classification is challenging because it requires contextual text understanding and a huge amount of labeled data. This paper proposes a novel method that jointly learns volitionality and subject animacy at a low cost, heuristically labeling events in a raw corpus. Volitionality labels are assigned using a small lexicon of volitional and non-volitional adverbs such as “deliberately” and “accidentally”; subject animacy labels are assigned using a list of animate and inanimate nouns obtained from ontological knowledge. We then consider the problem of learning a classifier from the labeled events so that it can perform well on unlabeled events without the words used for labeling. We view the problem as a bias reduction or unsupervised domain adaptation problem and apply the techniques. We conduct experiments with crowdsourced gold data in Japanese and English and show that our method effectively learns volitionality and subject animacy without manually labeled data.

Introduction
Volitionality is a fundamental property of an event that indicates whether someone is volitionally involved in the event. This study particularly focuses on volitionality with respect to the subject of an event. For example, “eating” and “writing” are usually volitional from the viewpoint of the subject, while “crying” and “getting injured” are non-volitional. Event volitionality classification has been used for causal knowledge categorization (Lee and Jun 2008; Inui, Inui, and Matsumoto 2003; Abe, Inui, and Matsumoto 2008a,b) and has various potential applications such as conditional event prediction (Du et al. 2019), script induction (Chambers and Jurafsky 2008), and customer feedback analysis (Liu et al. 2017).

On the other hand, animacy is a fundamental property of a noun that indicates whether the entity described by the noun is capable of human-like volition (Bowman and Chopra 2012). Since this study focuses on volitionality with respect to the subject of an event, it would be helpful to consider the animacy of the subject as a necessary condition for volitionality. Consequently, this study considers the event property of subject animacy. The close relationship between volitionality and subject animacy suggests a synergistic effect of joint learning.

The challenge of identifying volitionality and subject animacy lies in limited language resources and contextual dependence. The volitionality of an event is largely decided by its predicate. However, existing language resources such as ConceptNet (Speer, Chin, and Havasi 2017) do not provide an exhaustive list of volitional predicates. Even with a rich language resource, however, volitionality cannot be entirely identified due to its context-dependent nature. Let us consider the following Japanese examples.

(1) a. shawa-o abiru (V)
   shower-ACC take

b. hinan-o abiru (NV)
   criticism-ACC get

Example (1-a) and example (1-b) have the same predicate

1 ACC is the accusative case marker.
“abiru (take/get).” However, the former is volitional, while the latter is non-volitional. Similarly, example (2-a) is non-volitional, but example (2-b) is volitional because of the adverb “fukaku (deeply).”

(2) a. iki-o suru (NV)
   breath-ACC take
b. fukaku iki-o suru (V)
   deeply breath-ACC take

Coupled with the unbounded combinatorial nature of language, such context-dependent nature entails the demand for learning from a huge amount of labeled data.

As for subject animacy, although there exist some available language resources listing animate and inanimate nouns, they are far from exhaustive. Besides, subject animacy classification also requires contextual text understanding. For example, although example (3-a) and example (3-b) have the same subject, “shirobai (white motorcycle),” the former describes an inanimate entity (a motorcycle) while the latter describes an animate entity (a police officer) as metonymy.

(3) a. shirobai-ga tometearu (IA)
   white motorcycle-NOM be parked
b. shirobai-ga oikaketekaru (A)
   white motorcycle-NOM chase

In order to deal with these cases, it is inevitable to build a classifier that is capable of contextual understanding, which requires large amounts of labeled data for training.

This paper proposes a minimally supervised method to learn volitionality and subject animacy jointly. Figure 1 illustrates the overview of our method. We first heuristically assign labels to events in a raw corpus. Volitionality labels are assigned using a small lexicon of volitional and non-volitional adverbs, collectively called the volitionality indicating words. For example, example (4) is regarded as volitional because the volitional adverb “aete (deliberately)” modifies the predicate.

(4) aete shinjitsu-o hanasu (V)
   deliberately truth-NOM tell

Example (5) is considered non-volitional because the non-volitional adverb “ukkari (accidentally)” modifies the predicate.

(5) ukkari keitai-o otosu (NV)
   accidentally mobile-ACC drop

Subject animacy labels are assigned using a list of animate and inanimate nouns, collectively called the animacy indicating words, obtained from ontological knowledge. Using this labeling method, a large number of labeled events can be collected at a low cost.

As example (4) and example (5) suggest, we can assume that the volitionality of an event is preserved after removing the volitionality indicating words in most cases. The same can be said for subject animacy.

However, this is not always true. For example, example (6-a) is volitional, but example (6-b) is non-volitional. Here, the volitionality indicating word “aete (deliberately)” plays an essential role.

(6) a. aete kokeru (V)
   deliberately tumble
b. kokeru (NV)
   tumble

Such cases also exist in subject animacy classification. For example, the subject of example (7-a) “shogeiki (impact)” is inanimate, but the omitted subject of example (7-b) is normally assumed to be animate. In example (7-a), a classifier needs to focus on the subject to make a correct prediction.

(7) a. shogeiki-ga hashiru (IA)
   impact-NOM run
b. hashiru (A)
   run

Taking into account these properties, we learn a classifier. Given that labels are generally preserved after removing the volitionality/animacy indicating words, we learn classification on labeled events with regularization to prevent the classifier from focusing such words, making the classifier generalize to unlabeled events that do not contain such words. Although there exist exception cases where labels change by removing the volitionality/animacy indicating words, we expect that such cases are learned from data by building the classifier on top of the generalized vector representations of events produced by a general-purpose language model, BERT (Devlin et al. 2019).

We view the problem of restricting a classifier from focusing on the volitionality/animacy indicating words as a bias reduction (Kennedy et al. 2020; Jin et al. 2020) or unsupervised domain adaptation (Ramponi and Plank 2020) problem and utilize the methods as regularization. In bias reduction, the volitionality/animacy indicating words are regarded as bias that should not be over-exploited to make predictions. During training, the classifier learns to reduce the contribution of the words towards predictions. In unsupervised domain adaptation, labeled events and unlabeled events are considered source domain data and target domain data, respectively. Through training to make the classifier perform well on unlabeled data, it is expected that the classifier learns not to solely rely on the volitionality/animacy indicating words that are not available on unlabeled data.

We conduct experiments with crowdsourced gold data in Japanese and English and verify the effectiveness of the proposed method to learn volitionality and subject animacy without manually labeled data.

---

2 We use “V” and “NV” to indicate that an event is volitional and non-volitional from the viewpoint of the subject, respectively.

3 We use “A” and “IA” to indicate that the subject of an event is animate and inanimate, respectively.

4 NOM is the nominative case marker.

5 Our code and crowdsourced gold data are available at https://github.com/hkiyomaru/volcls.
Related Work

Our work mainly builds on event volitionality classification, bias reduction, and unsupervised domain adaptation.

Event Volitionality Classification

Previous work on event volitionality classification can be categorized into a targeted setting and a non-targeted setting. In the targeted setting, a model is given the predicate and its argument of an event and predicts whether the argument is volitionally involved in the action or state the predicate represents. This setting has been tackled as a sub-task of semantic proto-role labeling (Reisinger et al. 2015; White et al. 2016; Teichert et al. 2017).

In the non-targeted setting, which we tackle in this paper, a model is given an event and predicts whether the subject is volitionally involved in the event. To this end, Abe, Inui, and Matsumoto (2008a) and Abe, Inui, and Matsumoto (2008b) manually built a lexicon of verbs with volitionality labels and classified event volitionality by looking it up. This method is constrained by its inability to take context into account; as example (1-a) and example (1-b) suggest, volitionality depends on context.

Inui, Inui, and Matsumoto (2003) proposed a data-driven approach; they learned an SVM with hand-crafted linguistic features of events on a small amount of manually labeled data. However, the non-compositionality of event volitionality prevents us from learning from a small dataset. We use a massive amount of heuristically labeled events to learn a wide range of language phenomena and world knowledge related to volitionality.

Bias Reduction

Bias reduction is a technique to prevent a model from exploiting a specific bias to make predictions. While bias reduction has been actively studied in the field of fairness in machine learning (Bolukbasi et al. 2016; Zhao et al. 2017, 2019; Kennedy et al. 2020), we use this technique to prevent our model from over-exploiting the volitionality/animacy indicating words. Specifically, we employ two bias reduction methods proposed in Kennedy et al. (2020): word removal and explanation regularization based on sampling and occlusion (Jin et al. 2020). These methods were originally proposed to learn a hate speech classifier robust to group identifiers such as “gay.” The details are deferred to the section on the proposed method.

Unsupervised Domain Adaptation

It is reasonable to employ semi-supervised learning techniques to solve our problem because our training data contains both labeled and unlabeled events. In the context of semi-supervised learning, given that our primary focus is on classifying unlabeled events to which our heuristics cannot assign labels, our problem can be particularly viewed as an unsupervised domain adaptation (UDA) problem (Ramponi and Plank 2020).

UDA focuses on the setting where a model is required to perform well on a target domain using labeled data from a source domain and unlabeled data from the target domain. We employ UDA regarding labeled events and unlabeled events as source domain data and target domain data, respectively. Specifically, we employ adversarial domain adaptation (ADA) that has been used successfully in NLP tasks, including text classification such as sentiment analysis (Ganin et al. 2016; Ganin and Lempitsky 2015; Shah et al. 2018; Shen et al. 2018). In ADA, a model learns a latent feature space to reduce the discrepancy between the source and target distributions while learning a task using the source domain data, using an adversarial learning framework. The details are deferred to the section on the proposed method.

Problem Setting

This section describes the representation, scope, and annotation of events we target in the present paper.

Representation

We represent an event as a clause, that is, a text that contains one main predicate. Compared to structured representations such as predicate-argument structures (Gildea and Jurafsky 2000), clauses can more flexibly represent the meaning of events. Besides, by representing events by clauses, we can obtain powerful event representations using strong pretrained text encoders like BERT (Devlin et al. 2019).

Scope

This paper focuses on events whose volitionality cannot be identified by simple linguistic features: POS tags and voice. We use POS tags to filter out events whose predicates are either an adjective or copula because they always represent a state and thus never represent a volitional action, as shown in example (8) and example (9).

(8) sora-ga kireida [NV]
    sky-NOM be beautiful
(9) kare-wa gakuseida [NV]
    he-NOM be student

As for voice, we filter out events in the passive or potential voice because they are not volitional from the viewpoint of their subjects, as shown in example (10) and example (11).

(10) sensei-ni shikarareru [NV]
    teacher-DAT be scolded
(11) watashi-wa hashireru [NV]
    l-NOM can run

Besides, we filter out events with modality, a linguistic expression representing the writer’s opinion or attitude towards an event. Example (12) contains the modality of CERTAINTY expressed by “hazuda (should).”

(12) kare-wa kuru hazuda
    he-NOM come should

Because our focus is on recognizing the volitionality of an event itself, we exclude such an event from the scope.

6DAT is the dative case marker.
Annotation
An event is given volitionality and subject animacy labels.

Volitionality An event is considered volitional if the subject is volitionally involved in the event. Otherwise, it is considered non-volitional.

Subject Animacy The subject of an event is considered animate if the entity described by it can take volitional actions. Otherwise, it is considered inanimate. Note that we tie an animacy label to an event rather than the subject. We consider a model that is given an event and predicts its subject animacy.

Proposed Method
Our goal is to train a model that is given an event $x$ and predicts its volitionality $y_{vol}$ and subject animacy $y_{ani}$. Both $y_{vol}$ and $y_{ani}$ take the value of 1 if positive (volitional/animate) and 0 if negative (non-volitional/inanimate). First, labeled events are collected from a raw corpus with our heuristic labeling method. Then, our model jointly learns volitionality and subject animacy with regularization.

Constructing Training Dataset
We construct four types of datasets: events with volitionality labels $D_{vol}^l$, events without volitionality labels $D_{vol}^u$, events with subject animacy labels $D_{ani}^l$, and events without subject animacy labels $D_{ani}^u$.

First, events whose volitionality cannot be identified by simple linguistic features are extracted from a raw corpus using an off-the-shelf syntactic dependency parser and POS tagger. Each event is then given its volitionality and subject animacy labels by our heuristic labeling method. According to the given label, the event is added to the corresponding dataset.

To assign the volitionality label, we prepare a small lexicon of volitional and non-volitional adverbs. If an adverb in the lexicon modifies the predicate of the event, the event is given the corresponding label and added to $D_{vol}^l$. Otherwise, the event is added to $D_{vol}^u$ without being given a label.

To assign the subject animacy label, we first find the subject of the event using a semantic dependency parser. If the subject is found, its animacy is then examined by looking up the animacy indicating words obtained from ontological knowledge and using the result of named entity recognition. If the animacy is identified, the event is associated with the corresponding label and pushed into $D_{ani}^l$. If the subject is not found — which is not rare in pro-drop languages, including Japanese — or its animacy is not identified, the event is added to $D_{ani}^u$ without being given a label.

Model
Our model consists of the following three neural networks: a text encoder $E$, a volitionality classifier $C_{vol}$, and a subject animacy classifier $C_{ani}$. The text encoder transforms an event $x$ into a distributed representation. The volitionality classifier is given the representation and predicts the probability of $x$ being volitional. Likewise, the subject animacy classifier predicts the probability that the subject of $x$ is animate.

Training with Regularization
Our model jointly learns volitionality classification and subject animacy classification with regularization. As their training is done in a unified manner, we introduce placeholders for convenience. We refer to a labeled dataset as $D^l$, an unlabeled dataset as $D^u$, the label assigned to events in $D^l$ as $y$, and the classifier to predict $y$ as $C$. When learning volitionality, these placeholders are accompanied by the suffix “vol”; as for subject animacy, they are accompanied by the suffix “ani.”

Our model learns classification using the labeled dataset. Formally, the objective is written as follows:

$$\mathcal{L}_{cls} = \mathbb{E}_{(x,y) \sim D^l} \text{BCE}(y, C(E(x))),$$

where BCE is binary cross-entropy.

We explore the following regularization methods.

Word Removal (WR) WR is a bias reduction method that decreases reliance on a word to make predictions by removing the word from training data. We use this method to reduce reliance on the volitionality/animacy indicating words. The objective is written as follows:

$$\mathcal{L}_{WR} = \mathbb{E}_{(x,w) \sim D^l} \text{BCE}(y, C(E(x\setminus w))),$$

where $w$ is the volitionality/animacy indicating word in $x$ and $x\setminus w$ is $x$ from which $w$ is removed.

Explanation regularization by sampling and occlusion (SOC) SOC is a bias reduction method that penalizes the context-independent contribution of a word towards predictions (Kennedy et al. 2020). In order to estimate a context-independent contribution, SOC calculates the difference of model output after masking out the word, marginalized over all the possible context of the word. We use this method to reduce reliance on the volitionality/animacy indicating words. Formally, the objective is written as follows:

$$\mathcal{L}_{SOC} = \mathbb{E}_{x,S} \left[ \phi(x)^2 \right],$$

$$\phi(x) = \frac{1}{|S|} \sum_{x' \in S} [C(E(x')) - C(E(x\setminus w))]^2,$$

where $w$ is the volitionality/animacy indicating word in $x$, $S$ is a set of events created by sampling the context of $w$ according to a pretrained language model, and $x\setminus w$ is $x'$ that $w$ is replaced with a padding token.

Adversarial Domain Adaptation (ADA) ADA is an unsupervised domain adaptation technique (Ganin et al. 2016; Ganin and Lempitsky 2015). In ADA, a model learns to make the features of unlabeled data from a target domain closer to the features of labeled data from a source domain while learning a task using the labeled data. This training is done in an adversarial manner. During training, an additional neural network called discriminator $D$ is trained. The discriminator is given the output of the encoder and predicts 1 if the input is source domain data and 0 otherwise. The encoder learns to fool the discriminator. We use ADA considering the labeled dataset as source domain data and the unlabeled dataset as target domain data. Formally, the objective is written as follows:

$$\mathcal{L}_{ADA} = \mathbb{E}_{x \sim D^l} \text{BCE}(0, D(E(x))) + \mathbb{E}_{x \sim D^u} \text{BCE}(1, D(E(x))).$$
| Volitional | Non-volitional |
|-----------|---------------|
| **Japanese** | **English** |
| aete (5,293) | omowaza (18,115) | carefully (13,594) | unfortunately (13,070) |
| isode (4,187) | tsei (15,897) | thoroughly (12,468) | automatically (12,824) |
| jikkari (4,017) | jidouteki (14,212) | actively (10,379) | unexpectedly (5,272) |
| shinchi (3,743) | juto (12,050) | deliberately (3,366) | unexpectedly (3,106) |
| wazawaza (3,262) | tsutsu (10,054) | intentionally (2,713) | luckily (1,894) |

Table 1: The five most frequent volitionality indicating words in our lexicon. The numbers in parentheses indicate frequency.

| \( \mathcal{D}_{\text{vol}} \) | \( \mathcal{D}_{\text{vol}} \) | \( \mathcal{D}_{\text{ani}} \) | \( \mathcal{D}_{\text{ani}} \) |
|---|---|---|---|
| Japanese | 78.2 | 76.9 | 77.2 | 74.3 |
| English | 62.4 | 62.8 | 66.8 | 67.1 |

Table 2: The inter-annotator agreement rate for each dataset, calculated by averaging the ratios of majority answers.

**Consistency (CON)** \( \mathcal{L}_{\text{CON}} = \mathbb{E}_{x \sim \mathcal{D}_{\text{vol}}} \max(0, C_{\text{vol}}(E(x)) - C_{\text{ani}}(E(x))) \). (6)

These regularization objectives are combined with the classification objective with a weight. Our training objective is finally written as follows:

\[ \mathcal{L} = \mathcal{L}_{\text{cls}} + \alpha \mathcal{L}_{\text{WR|SOC|ADA}} + \beta \mathcal{L}_{\text{CON}}, \] (7)

where \( \alpha \) and \( \beta \) are weights selected as hyper-parameters and \( \mathcal{L}_{\text{WR|SOC|ADA}} \) is either \( \mathcal{L}_{\text{WR}}, \mathcal{L}_{\text{SOC}}, \) or \( \mathcal{L}_{\text{ADA}} \).7

**Experiments**

**Training Dataset**

**Japanese** We used 30M documents in CC-100 as a raw corpus (Conneau et al. 2020; Wenzek et al. 2020). Events were parsed and extracted using KN Ped, a widely used Japanese parser (Kawahara and Kurohashi 2006). For volitionality labeling, we manually constructed a lexicon of representative and frequent volitional/non-volitional adverbs. We used 15 volitional and 15 non-volitional adverbs (Table 1). For animacy labeling, we used the dictionary on which KN Ped builds as ontological knowledge. It contained approximately 30K nouns with animacy labels. We also used the named entity recognizer built into KN Ped to recognize animacy. We did not delete duplicate events to preserve frequency information.

**English** We again used 30M documents in CC-100 as a raw corpus. Events were parsed and extracted using spacy.9

---

7It is possible to combine WR, SOC, and ADA, in theory. We did not try that due to the computational cost.

9https://github.com/ku-nlp/JumanDIC

9https://spacy.io

For volitionality labeling, we manually constructed a lexicon of 10 volitional and 10 non-volitional adverbs (Table 1). For animacy labeling, we obtained animate and inanimate nouns from ConceptNet (Speer, Chin, and Havasi 2017). Specifically, we used the hyponyms of “person” and “organization” as animate nouns, and the hyponyms of “object,” “item,” “thing,” “artifact,” and “location” as inanimate nouns. As a result, we obtained 2,604 animate nouns and 430 inanimate nouns. Besides, we used the named entity recognizer built into spacy for animacy recognition.

**Evaluation Dataset**

We constructed an evaluation dataset for each of \( \mathcal{D}_{\text{vol}} \), \( \mathcal{D}_{\text{vol}} \), \( \mathcal{D}_{\text{ani}} \), and \( \mathcal{D}_{\text{ani}} \). We first randomly extracted 1,200 unique events from each of the datasets. We then assigned the ground truth to them by crowdsourcing. As for volitionality labeling, crowdworkers were given an event and assigned one of the following labels:

- The subject is volitionally involved in the event.
- The subject is not volitionally involved in the event.
- Unable to say either.
- Unable to understand.

As for animacy labeling, crowworkers were given an event and assigned one of the following labels:
- The subject is a person(s) or organization(s).
- The subject is neither a person(s) nor organization(s).
- Unable to say either.

Each event was annotated by five crowworkers. One crowworker annotated ten events. For Japanese, we used Yahoo! Crowdsourcing\[^{10}\] as a crowdsourcing platform. For quality control, we used the function provided in the platform to reject workers who made a mistake on an easy question that we manually prepared in advance. The total cost was 24,000 JPY. For English, we used Amazon Mechanical Turk.

---

\[^{10}\]https://crowdsourcing.yahoo.co.jp/
cal Turk (MTurk). For quality control, we followed common best practices (Berinsky, Huber, and Lenz 2012); workers had to have over a 95% acceptance rate, live in the US, and have done more than 1,000 tasks. The total cost was 288 USD.

Table 2 shows the inter-annotator agreement rates. Events with an agreement rate of 80% or more were extracted, and half were used for validation and the other half were used for testing. Table 3 summarizes the constructed datasets.

Implementation Detail

The encoder was pretrained BERTBASE (Devlin et al. 2019). We used the output of the classification token ([CLS]) as event representations. The classifiers were a three-layered fully-connected neural network with the ReLU nonlinearity followed by the sigmoid function. The discriminator used in Ada had the same architecture as the classifiers. SOC was used with a sample size of three. α was selected from {0.0, 0.01, 0.1, 1.0} for each of WR, SOC, and ADA. β was selected from {0.0, 0.01, 0.1, 1.0}. We trained the model for three epochs with a batch size of 256. We used the Adam optimizer (Kingma and Ba 2015) with a learning rate of 3e-5, linear warmup of the learning rate over the first 10% steps, and linear decay of the learning rate. We evaluated the performance on the development dataset of $D^\text{val}_{\text{vol}}$, which was our primary concern, at every 100 steps, and adopted the checkpoint that achieved the best performance. The evaluation metric was the AUC of the ROC curve. Models were trained three times with different random seeds. We used Pytorch for implementation.

Results

Table 4 shows the result. In both Japanese and English, joint learning combined with regularization achieved the best performance on both volitionality and subject animacy classification on the unlabeled datasets and most of the labeled datasets. Specifically, when joint learning was employed, SOC was constantly effective to learn volitionality classification. Without joint learning, the models trained with ADA often performed best.

As for subject animacy classification, the effective method depended on language. This is likely because Japanese is a pro-drop language while English is not. In Japanese, the most effective method was WR. Learning subject animacy of events produced by WR can be interpreted as learning animacy of omitted subjects. Events with omitted subjects were not given a subject animacy label by our labeling method and thus were in $D^\text{val}_{\text{ani}}$. The models trained with WR successfully generalized to such events. In English, on the other hand, because subjects are not omitted, WR was not as effective as in Japanese.

We observed that the overall scores on the English datasets were lower than the Japanese ones. The reason was the quality of the evaluation datasets. As Table 2 suggests, the English evaluation datasets were constructed by crowdworkers with a lower agreement rate. Investigating the output manually, we found that the performance was underestimated due to labeling mistakes in the gold data.

Qualitative Analysis

We investigated what is learned by our method, using the model that best performed on $D^\text{val}_{\text{vol}}$. While we had three models trained with the same setting with different random seeds, we used one that achieved the second-best validation performance for analysis.

Japanese The best performing model learned volitionality with SOC, subject animacy with WR, and prediction consistency with CON. We found that the model was aware of context. Example (1-a) and (1-b) were successfully classified as volitional and non-volitional, respectively, though these events had the same predicate. Example (2-a) and (2-b) were again correctly classified as non-volitional and volitional, respectively, considering the meaning of the adverb. We observed that subject animacy was also recognized considering context; the subjects of example (3-a) and (3-b) were successfully classified as inanimate and animate, respectively. It would be interesting to quantitatively evaluate such context-awareness by constructing a dataset like Winograd Schema Challenge (Levesque, Davis, and Morgenstern 2012).

We found that there still existed verbs that our model struggled with recognizing the volitionality. One notable verb was “iru (exist/stay).” While the verb “iru (exist/stay)” basically represents a state, it can represent a volitional action when the subject is animate. We speculate that the difficulty of recognizing the animacy of omitted subjects also contributed to this problem. A plausible solution is to consider the preceding and following events during training. If the meaning of an event is different, the distribution of its surrounding events should be too. Learning such contextual differences could lead to better performance.

English The best performing model learned volitionality with SOC, subject animacy with SOC, and prediction consistency with CON. We again found that the model successfully performed classification considering context. For example, the following examples with the same predicate “made” were correctly classified.

(13) a. I made pancakes. (V)
   b. I made a mistake. (NV)

The following examples were also successfully classified, capturing the meaning of the adverbial phrase “for him.”

(14) a. I tumbled. (NV)
   b. I tumbled for him. (V)

Quality of Labeled Data

Because we had heuristically and automatically assigned labels to events, our labeled datasets should contain wrongly labeled events. However, if the datasets were full of errors, it is likely to fail to learn classification.

Given the fact that we could learn a classifier with fairly good performance, we report the quality of our labeled data as a reference for applying our method to other languages. We randomly extracted 100 unique positive and negative events from each of $D^\text{val}_{\text{vol}}$ and $D^\text{val}_{\text{ani}}$, and manually examined
whether they were given a correct label or not. We considered that events incomprehensible for some reason (e.g., parsing error) were not given a correct label.

Table 5 shows the result. We found that most events were labeled correctly. Japanese negatively-labeled events in $D^j_{\text{ani}}$ had relatively low accuracy. While English, negatively-labeled events in $D^e_{\text{ani}}$ had relatively low accuracy. While there were several reasons, one of them was that, although we regarded nouns representing a location as inanimate, they sometimes represented an organization (e.g., country name).

### Conclusion
This paper focused on the close relationship between volitionality and animacy and proposed a method to jointly learn them with regularization in a minimally-supervised manner. Experiments in Japanese and English showed the effectiveness of the proposed method to learn volitionality and subject animacy without manually labeled data.

There have been few studies using volitionality classification. This is partly because there was neither a readily available volitionality classifier nor a method to create a volitionality classifier at a low cost. We hope this study facilitates future research that builds on volitionality classification.
