ABSTRACT
We present the results of two-dimensional and three-dimensional magnetohydrodynamical numerical simulations of relativistic magnetic reconnection, with particular emphasis on the dynamics of the plasma in a Petschek-type configuration with high Lundquist numbers, $S \sim 10^5 - 10^8$. The numerical scheme adopted, allowing for unprecedented accuracy for this type of calculations, is based on high order finite volume and discontinuous Galerkin methods as recently proposed by Dumbser & Zanotti (2009). The possibility of producing high Lorentz factors is discussed, showing that Lorentz factors close to $\sim 4$ can be produced for a plasma parameter $\sigma_m = 20$. Moreover, we find that the Sweet-Parker layers are unstable, generating secondary magnetic islands, but only for $S > S_c \sim 10^8$, much larger than what is reported in the Newtonian regime. Finally, the effects of a mildly anisotropic Ohm law are considered in a configuration with a guide magnetic field. Such effects produce only slightly faster reconnection rates and Lorentz factors of about 1% larger with respect to the perfectly isotropic Ohm law.

Key words: plasmas, magnetohydrodynamics, relativity

1 INTRODUCTION
Relativistic magnetic reconnection is recognized to be a key physical process in high-energy astrophysics, being able to convert magnetic energy into heat and plasma kinetic energy over short timescales. Relevant examples include: (i) the magnetospheres of pulsars near the Y-point, where the outermost magnetic field lines intersect the equatorial plane (Uzdensky 2003; Gruzinov 2005); (ii) the dissipation of alternating fields at the termination shock of a relativistic striped pulsar wind (Petri & Lyubarsky 2007); (ii) soft gamma-ray repeaters, where giant magnetic flares could be the explanation of the observed strongly magnetized and relativistic ejection events (Lyutikov 2003, 2004); (iv) gamma-ray burst jets, where particle acceleration by magnetic reconnection in electron-positron plasmas is supposed to take place (Drenkhahn & Spruit 2002; Barkov & Komissarov 2010; McKinney & Uzdensky 2010; Rezzolla et al. 2011); (v) and accretion disc coronae of active galactic nuclei, where violent releases of energy may be generated by Petschek magnetic reconnection of strong magnetic loops emerging from the disc via buoyancy instability (di Matteo 1998; Schopper et al. 1998; Jaroschek et al. 2001). Very recently, moreover (Nalewajko et al. 2011) have described a model of mini jets in blazars to explain their ultra-fast variability and were able to fit data of PKS2155-304 assuming that the dynamics is governed by relativistic magnetic reconnection with a weak “guide magnetic field”, i.e. with a magnetic field aligned to the current.

In the recent past, both theoretical studies and numerical investigations have greatly improved our understanding of relativistic magnetic reconnection. Although within the incompressibility assumption, Lyutikov & Uzdensky (2003) first found that in the Sweet-Parker reconnection three different regimes can be produced, which depend on the ratio of the magnetization parameter $\sigma_m$ to the Lundquist number $S$, Lyubarsky (2005), on the other hand, explicitly addressed the question about whether the reconnection rate can be significantly enhanced or not in the transition from Newtonian to relativistic magnetic reconnection. He found that, unless the reconnecting fields are not strictly antiparallel, the relativistic Petschek reconnection should not be considered as a mechanism for the direct conversion of the magnetic energy into the plasma energy and the reconnection rate would be at most 0.1 the speed of light, contrary to what originally suggested by Blackman & Field (1994). Moreover, Tolstyk et al. (2007) extended the Petschek reconnection model to incorporate relativistic effects of impulsive reconnection and, for current layers embedded into
strong magnetic fields, they claimed that the plasma can be accelerated to high Lorentz factors.

Because our understanding of relativistic magnetic reconnection is still incomplete, in the last few years there has been a growing expectation towards numerical simulations as a promising tool for clarifying the rich underlying physics, particularly in the non-linear regime. After the pioneering resistive relativistic simulations by [Watanabe & Yokoyama (2004)], who considered the Petschek type reconnection in the relativistic regime with a resistive magnetohydrodynamic (MHD) code, [Zenitani et al. (2009)] investigated the relativistic reconnection in an electron-positron plasma by a two-fluid MHD code and showed that the reconnection rate is higher and higher in magnetically dominated regimes. [Zenitani et al. (2009)], on the other hand, clarified the role of a guide magnetic field, which is essentially that of making the output energy flux Poynting dominated rather than enthalpy dominated. Very recently, [Zenitani et al. (2010)] showed that, when the resistivity is current dependent, plasmoids are repeatedly formed in the current sheet. In spite of these progresses, two major numerical limitations still prevent the application of numerical calculations to realistic physical and astrophysical scenarios in the relativistic regime. The first limitation manifests when treating plasmoids with high magnetization parameters $\sigma$, while the second limitation manifests when high Lundquist numbers $S$ are encountered, being related to the stiffness of the equations in this regime. Physically, high Lundquist number plasmoids are very interesting as they are supposed to become unstable and break up into secondary magnetic islands. In the Newtonian framework, for example, [Samtaney et al. (2006)] showed that Sweet-Parker current sheets are unstable and break up into secondary magnetic islands.

In the Newtonian framework, for example, [Samtaney et al. (2006)] considered the Petschek type reconnection in a regime characterized by high Lundquist numbers, $S > S_0$, focusing, in particular, on the dynamics of the plasma in the non-linear regime. After the pioneering work by [Dumbser & Zanotti (2006)], who considered the Petschek type reconnection in a regime characterized by high Lundquist numbers, $S > S_0$, focusing, in particular, on the dynamics of the plasma in the non-linear regime. After the pioneering work by [Dumbser & Zanotti (2006)], we reconstructed this instability persists in a relativistic framework.

The plan of the paper is the following. In Section 2 we report the relativistic resistive equations and the basic physical assumptions, while Section 3 is devoted to a succinct presentation of the numerical method and to the validation of the code in three space dimensions. Section 4 contains the results of our analysis, and Section 5 the conclusions. We have considered only flat spacetimes in pseudo-Cartesian coordinates, namely the metric $g_{\mu\nu} = \text{diag}(-1, 1, 1, 1)$, where from now onwards we agree to use Greek letters $\mu, \nu, \lambda, \ldots$ (running from 0 to 3) for indices of four-dimensional spacetime tensors, while using Latin letters $i, j, k, \ldots$ (running from 1 to 3) for indices of three-dimensional spatial tensors. We set the speed of light $c = 1$ and make use of the Lorentz-Heaviside notation for the electromagnetic quantities, such that all $\sqrt{-g}$ factors disappear. Finally, we use Einstein summation convention over repeated indices.

2 MATHEMATICAL FORMULATION

The total energy-momentum tensor of the plasma that we consider is made up by two contributions, $T_{\mu\nu} = T_{m\mu\nu} + T_{f\mu\nu}$. The first one is due to matter

$$T_{m\mu\nu} = h\rho u^\mu u^\nu + p u^\mu u^\nu,$$

where $u^\mu$ is the four velocity of the fluid, while $h$, $\rho$ and $p$ are the specific enthalpy, the rest mass density and the pressure as measured in the co-moving frame of the fluid. The second contribution comes from the electromagnetic field

$$T_{f\mu\nu} = F^\mu\lambda F^{\nu\lambda} - \frac{1}{4} (F^{\lambda\kappa} F_{\lambda\kappa}) n^\mu n^\nu,$$

where $F^{\mu\nu}$, and its dual $F^{*\mu\nu}$, is the electromagnetic tensor given by

$$F_{\mu\nu} = \varepsilon_{\mu\nu\lambda\kappa} B^{\lambda\kappa} / 2,$$

$$F^{*\mu\nu} = \varepsilon_{\mu\alpha\beta\kappa} E^{\alpha\beta} / 2,$$

$E^{\alpha}$ and $B^{\alpha}$ are the electric and magnetic field as measured by the observer defined by the four-velocity vector $u^\alpha$, while $\varepsilon_{\mu\nu\lambda\kappa}$ is the completely antisymmetric spacetime Levi-Civita tensor, with the convention that $\varepsilon^{0123} = 1$. If we now set $n^\mu$ to define the inertial laboratory observer, namely $n^\mu = (1, 0, 0, 0)$, normalized such that $n^\mu n_\mu = -1$, then the four vectors of the electric and of the magnetic field are purely spatial, i.e. $E^0 = B^0 = 0$, $E^i = E_i$, $B^i = B_i$ in this frame. On the other hand, the fluid four velocity $u^\mu$ and the standard three velocity in the laboratory frame are related as $\vec{v} = v^i = u^i / \Gamma$, where $\Gamma = (1 - \vec{v}^2)^{-1/2}$ is the Lorentz factor of the fluid with respect to the laboratory frame.

In Cartesian coordinates, using the abbreviations $\partial_i = \partial / \partial x_i$ and $\partial_t = \partial / \partial t$, the full system of Euler and Maxwell equations are

$$\partial_t D + \partial_i (D v^i) = 0,$$

$$\partial_t S_i + \partial_j Z^i_j = 0,$$

$$\partial_t \rho + \partial_i S^i = 0,$$

$$\partial_t E^i - \varepsilon^{ijk} \partial_j B_k + \partial_i \Psi = -J^i,$$

$$\partial_t B^i + \varepsilon^{ijk} \partial_j E_k + \partial_i \Phi = 0,$$

$$\partial_i \Psi + \partial_j E^j = \rho_\rho - \kappa \Psi,$$

$$\partial_i \Phi + \partial_j B^j = -\kappa \Phi,$$

$$\rho_\rho + \partial_j J^j = 0,$$

where the conservative variables of the fluid are

$$D = \rho \Gamma,$$

$$S^i = \omega T^2 v^i + \varepsilon^{ijk} E_j B_k,$$

$$\tau = \omega T^2 - \rho + \frac{1}{2} (E^2 + B^2),$$

expressing, respectively, the relativistic mass density, the momentum density and the total energy density. The spatial tensor $Z^i_j$ in (11) representing the momentum flux density, is

$$Z^i_j = \omega T^2 v^i v_j - E^i E_j - B^i B_j + \left[ \rho + \frac{1}{2} (E^2 + B^2) \right] \delta^i_j,$$

where $\omega = h \rho$ is the enthalpy of the fluid while $\delta^i_j$ is the Kronecker delta. An equation of state is needed to close the system, and we have chosen that of an ideal gas, namely

$$p = (\gamma - 1) \rho e = \gamma_1 (\omega - \rho),$$

where $\gamma$ is the specific heat ratio and $\omega = h \rho$ is the enthalpy of the fluid.
where γ is the adiabatic index, γt = (γ − 1)/γ, ϵ is the specific internal energy.

While writing equations (10) and (11), we have adopted the so called divergence-cleaning approach presented in [Dehnen et al. (2002)], which amounts to introducing two additional scalar fields Ψ and Φ that propagate away the deviations of the divergences of the electric and of the magnetic fields from the values prescribed by Maxwell’s equations. Additional details about this approach can be found in [Komissarov (2007) and Palenzuela et al. (2008)].

In its most general form, the relativistic formulation of Ohm law is a non-linear propagation equation (Kandus & Tsagas [2008]), which makes it manifest the connection between the Ohm law and the equations of motion. However, in order to keep the equations numerically tractable and because of the poor knowledge of the conductivity in realistic conditions, simpler forms of the Ohm law are usually considered, in which the currents are algebraically related to the electromagnetic field. Following Bekenstein & Oron [1978] we allow for an anisotropic Ohm law and therefore we write the four-current vector as

\[ I^\mu = q_0 u^\mu + \sigma^{\mu\nu} e_\nu, \]

where \( q_0 \) is the charge density in the co-moving frame of the plasma, \( \sigma^{\mu\nu} \) is the conductivity tensor and \( e_\nu \) is the electric field in the co-moving frame. Within the collision-time approximation the most general form of the conductivity tensor is given by

\[ \sigma^{\mu\nu} = \sigma (g^{\mu\nu} + \xi^2 b^\mu b^\nu + \xi \epsilon^{\mu\nu\lambda\kappa} u_\lambda b_\kappa) \]

where \( u^\mu \) is the four velocity of the plasma and \( b^\mu \) is the magnetic field in the co-moving frame. The parameter \( \xi \) is related to the micro-physics of the plasma (Bekenstein & Oron [1978]) via \( \xi = \epsilon \tau / m_e \), where \( \epsilon \) and \( m_e \) are electron's charge and mass, while \( \tau \) is the collision time. As a first application to the case of an anisotropic Ohm law, in this paper we consider the case \( \sigma^{\mu\nu} = \sigma (g^{\mu\nu} + \xi^2 b^\mu b^\nu) \), namely we drop the third term in (19). We note, therefore, that anisotropic effects in the Ohm law are more and more important as the intensity of the magnetic field is increased. The four-current vector can also be decomposed in components parallel and perpendicular to the observer as \( I^\mu = \rho_e n^\mu + J^\mu \), where \( \rho_e \) is the charge density in the laboratory frame. Hence, it is easy to use in Eq. (3), namely

\[ \vec{J} = \rho_e \vec{v} + \Gamma \sigma (\vec{E} + \vec{v} \times \vec{B}) - (\vec{E} \cdot \vec{v}) \vec{v} + \Gamma \sigma \epsilon^2 (\vec{E} \cdot \vec{B}) [\vec{B} - \vec{v} \times \vec{E} - (\vec{B} \cdot \vec{v}) \vec{v}], \]

(20)

Two relevant comments are worth doing about the Ohm law (20). The first and most obvious one is that the isotropic regime is recovered when \( \xi = 0 \), in which case Eq. (20) reduces to the usual expression (Komissarov [2007]). The second comment is that, in the comoving frame, the Ohm law (20) becomes

\[ \vec{J} = \sigma \vec{E} + \sigma \epsilon^2 (\vec{E} \cdot \vec{B}) \vec{B} \]

(21)

which clarifies how the current term proportional to \( \epsilon^2 \) is present only for configurations for which \( \vec{E} \cdot \vec{B} \neq 0 \) and it is responsible for an extra current term in the direction parallel to the magnetic field.

3 NUMERICAL METHOD

3.1 Brief description

A well known and challenging feature of the system of equations (3)-(12) is that it has source terms in the three equations (8) for the evolution of the electric field that become stiff in the limit of high conductivity. This pathology has been handled in the recent past by resorting to Strang-splitting techniques (Komissarov [2007]) or to implicit-explicit Runge Kutta methods (Palenzuela et al. [2004]). In the present paper, on the other hand, we apply the strategy outlined by Dumbser & Zanotti [2009], who used the so called high order \( P_N P_M \) methods, which are a unification of high order finite volume and discontinuous Galerkin finite element schemes in a more general framework, and combining results from Dumbser et al. [2008] and Dumbser et al. [2008]. It is worth stressing that, because of the high accuracy they allow to achieve, Galerkin methods have been recently considered as a valuable approach even in fully relativistic calculations. Promising results have been obtained by Zumbusch (2009) and Radice & Rezzolla (2011).

In our specific implementation, the numerical solution

![Figure 1](image1.png)

Figure 1. Numerical grid of the 3D simulation in the current sheet test. The \( B^\mu \) component of the magnetic field is reported.

![Figure 2](image2.png)

Figure 2. Comparison of the numerical solution with the analytic one in the 3D current sheet test. The plot shows a one-dimensional cut of the magnetic field \( B^\mu \) at time \( t = 10 \).
of the vector of conserved quantities is represented at the beginning of each time-step by polynomials of degree $N$. However, the time evolution of these data and the computation of the corresponding numerical fluxes are performed with a different set of piecewise polynomials of degree $M \geq N$, which are reconstructed starting from the underlying $N$ degree polynomials. The part of the algorithm performing the time evolution of the reconstructed polynomials uses a local polynomial degree of the polynomials in the part of the algorithm performing the time evolution of the reconstructed polynomials uses a local polynomial degree.

We have adopted a third order $P_1P_2$ finite volume scheme introduced by Watanabe & Yokoyama (2006) and by Zenitani et al. (2009a,b). Gas pressure and density are given by $p = p_0 + \sigma_n p_0 |p_0\cosh(2x)|^{-3}$, $\rho = \rho_0 + \sigma_n p_0 |p_0\cosh(2x)|^{-1}$, where $p_0$ and $\rho_0$ are the constant values outside the current sheet, whose thickness is $\delta = 1$. The magnetic field validation of the code by considering the numerical evolution of a self similar current sheet in three spatial dimensions. This configuration, first proposed by Komissarov (2007), has the following exact analytical solution for the $y$-component of the magnetic field:

$$B_y(x, t) = B_0 \text{erf} \left( \frac{1}{2} \sqrt{\frac{\sigma}{T^2}} \right),$$

(22)

where erf is the error function. The initial time for this test case is chosen to be $t = 1$ and the initial condition at $t = 1$ is given by $\rho = 1$, $p = 50$, $\vec{E} = \vec{v} = 0$ and $\vec{B} = (0, B_0(x, 1), 0)^T$. We choose $\gamma = \frac{4}{3}$ and $B_0 = 1$. The conductivity is set to $\sigma = 100$, which means a moderate resistivity. We have solved the problem with the fourth order $P_1P_2$ scheme on a very coarse unstructured mesh composed by 3209 tetrahedrons. The grid extension is given by $[-1.5, 1.5] \times [-0.5, 0.5] \times [-0.25, 0.25]$ and it is shown in Fig. 1 with a color rendering of the component $B_y$ of the magnetic field. Fig. 2 on the other hand, shows the perfect matching of the numerical solution against the analytic one at time $t = 10$ and computed along a representative one-dimensional cut of the numerical domain. We have also verified that the method provides the expected order of accuracy when the order of the polynomials in the $P_NP_M$ scheme is changed. This concludes the validation of the code in the full three-dimensional case.

### 4 MAGNETIC RECONNECTION

#### 4.1 Initial model and boundary conditions

The initial model that we have considered in our analysis of relativistic magnetic reconnection is built on Harris model, as reported by Kirk & Skjæraasen (2003), and it reproduces a current sheet configuration in the $x-y$ plane. Very similar configurations have been studied also by Watanabe & Yokoyama (2006) and by Zenitani et al. (2009a,b). Gas pressure and density are given by $p = p_0 + \sigma_n p_0 |p_0\cosh(2x)|^{-3}$, $\rho = \rho_0 + \sigma_n p_0 |p_0\cosh(2x)|^{-1}$, where $p_0$ and $\rho_0$ are the constant values outside the current sheet, whose thickness is $\delta = 1$. The magnetic field

| Model       | $\sigma_m$ | $S$     | $\eta_0$ | $B_x/B_0$ | cells | $L_{\min}$ |
|-------------|------------|---------|----------|-----------|-------|------------|
| 2D=m1-S1.60e5 | 1.0        | 1.60 x 10^5 | 10^-3    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m5-S2.45e5 | 5.0        | 2.45 x 10^5 | 10^-3    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m10-S2.68e5 | 10.0      | 2.68 x 10^5 | 10^-3    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m15-S2.77e5 | 15.0      | 2.77 x 10^5 | 10^-3    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m20-S2.82e5 | 20.0      | 2.82 x 10^5 | 10^-3    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m10-S2.68e6 | 10.0      | 2.68 x 10^6 | 10^-4    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m10-S2.68e7 | 10.0      | 2.68 x 10^7 | 10^-5    | 0.0       | 841944 | 4.90 x 10^-3 |
| 2D=m10-S2.68e8 | 10.0      | 2.68 x 10^8 | 10^-6    | 0.0       | 841944 | 4.90 x 10^-3 |
| 3D=m1.25-Bz0  | 1.25      | 1.73 x 10^4 | 0.005    | 0.0       | 6105345 | 2.49 x 10^-2 |
| 3D=m1.25-Bz0.5 | 1.25      | 1.73 x 10^4 | 0.005    | 0.5       | 6105345 | 2.49 x 10^-2 |

The beginning of each time-step is performed by constructing the global predictor $P_N$ scheme is changed. Once computed, the local space-time predictors are then inserted into a global corrector, which is fully explicit and provides the coupling between neighboring cells. The resulting Galerkin scheme can allow for an arbitrary (at least in principle) order of convergence, through a one-step and quadrature free time update (no need for Runge Kutta time stepping) formula. Within this new approach, traditional finite volume schemes with $N = 0$ and usual discontinuous Galerkin methods with $N = M$ are included as special cases, while the new class of methods with $N \neq 0, M > N$ are in general computationally more efficient. In most of the numerical simulations reported in this paper we have adopted the schemes $P_1P_2$, $P_1P_2$ and $P_1P_3$.

### 3.2 Validation of the code in three dimensions

In Dumbser & Zanotti (2006) we presented a wide class of numerical tests both in one and in two spatial dimensions, showing the ability of the scheme in dealing with the stiff terms inherent in the resistive relativistic equations, while retaining its high order properties. Here we complete the full
changes orientation across the current sheet according to $B_y = B_0 \tanh(2x)$, where the value of $B_0$ is given in terms of the magnetization parameter $\sigma_m = B_0^2/(2\rho_0 \Gamma^2)$. All over the grid there is a small background uniform resistivity $\eta_b$, except for a circle of radius $r_\eta = 0.8$, defining a region of anomalous resistivity of amplitude $\eta_\alpha = 1.0$. As a result, the resistivity can be written as

$$
\eta = \begin{cases} 
\eta_b + \eta_\alpha [2(r/r_\eta)^3 - 3(r/r_\eta)^2 + 1] & \text{for } r \leq r_\eta, \\
\eta_b & \text{for } r > r_\eta,
\end{cases}
$$

(23)

where $r = \sqrt{x^2 + y^2}$. The velocity field is initially zero, hence $\Gamma_0 = 1$, while the electric field is given by $E_z = \eta(\partial B_y/\partial x)$. In most of our simulations we have considered the case with $p_0 = 1$, $\rho_0 = 1$. The numerical grid consists of an unstructured mesh composed of triangles in 2D and tetrahedrons in 3D, which are clustered along the current sheet. The grid extension is given by $[-50, 50] \times [-150, 150]$ in 2D and by $[-50, 50] \times [-75, 75] \times [-12.5, 12.5]$ in 3D. Tab. 1 reports the basic parameters of the models studied in our simulations. The Lundquist number $S = v_A L/\eta_b$ is reported in the fourth column, where $L$ is the length of the initial current sheet, while $v_A = B^2/(\mu_0 + B^2)$ is the relativistic Alfvén velocity (Komissarov 1997, Del Zanna et al. 2007). The name of the models have been chosen to facilitate recognizing their main parameters. For example, model 2D-m10-S2.68e5 is a two dimensional model with magnetization $\sigma_m = 10$ and Lundquist number $S = 2.68 \times 10^5$ (corresponding to $\eta_b = 10^{-5}$). We have used periodic boundary conditions at $y_{\min}$ and $y_{\max}$, while zeroth order extrapolation is applied at $x_{\min}$ and $x_{\max}$.

### 4.2 Results

In a first series of simulations we have considered the case of an isotropic Ohm law, namely adopting Eq. (20) with $\xi = 0$, concentrating on the effects that an increasing magnetization produces on the system. Fig. 3 shows the rest mass density and the magnetic field lines for the model 2D-m1-S1.68e5 with $\sigma_m = 1.0$ (left panel) and for the model 2D-m20-S2.68e5 with $\sigma_m = 20$ (right panel). The two panels, which show snapshots of the two models at the same time $t = 90$, confirm the essential features of a Petschek-type relativistic reconnection, as also reported by other authors (Watanabe & Yokoyama 2006, Zenitani et al. 2009b,a). Namely, magnetic reconnection is triggered in the region of anomalous resistivity, producing the typical $X$-type topology of the magnetic field. As a result, magnetic energy is converted into both thermal and kinetic energy, and two plasmoids moving in opposite directions, and corresponding to the two high-density regions of the figure, are accelerated along the direction of the magnetic field. The magnetic tension, in fact, is responsible for the collimation of the flow. The plasmoid is highly compressed by plasma with much higher velocity and lower density (see the discussion about Fig. 5 below) and its rest mass density increases with increasing magnetization. A complementary information to that of Fig. 3 is provided by Fig. 4. The top and the middle panels show, respectively, the time evolution of the magnetic energy (normalized to its initial value) and of the Lorentz factor of the plasmoid, which is also the maximum Lorentz factor monitored over the grid. The dissipated magnetic energy produces an increase of both the thermal and kinetic energy. The latter results in the acceleration of the plasmoid,
See Zenitani et al. (2009b) for alternative definitions of the reconnection rate.

The reconnection rate, namely the speed at which the reconnection process takes place and that we have computed as \( r = E_z / B_0 \), is also strongly dependent on the magnetization, as firstly noticed by Watanabe & Yokoyama (2006).

We have followed its temporal evolution and found that it reaches a maximum around \( t \sim 20 - 30 \), while decreasing asymptotically after that to reach a stationary value. The maximum reconnection rate is \( r \sim 0.07 \) and \( r \sim 0.2 \) for models with \( \sigma_m = 1.0 \) and \( \sigma_m = 20 \), respectively. It should be noted that the regions of maximum rest mass density and of maximum Lorentz factor do not match exactly. The mismatch is reported in Fig. 5 which provides a focus of the upper plasmoid that is visible in the right panel of Fig. 6. The left and the right panels of Fig. 5 show the rest mass density and the Lorentz factor, respectively. As it is apparent from this figure, the plasma reaches its maximum velocity at the basis of the plasmoid in a very rarefied region. On the other hand, the portion of the plasmoid with maximum rest mass density has very low Lorentz factor. As a result, a tiny bow shock is produced at the basis of the plasmoid, confirming similar findings by Zenitani et al. (2010) who performed a detailed analysis of the generation of slow shocks around the plasmoids.

In a second series of simulations, we have analyzed the dependence of the reconnection process on the background Lundquist number \( S \), while keeping the same peak value of the anomalous resistivity \( \eta_{\alpha 0} = 1.0 \) and of the magnetization parameter \( \sigma_m = 10 \). It is worth recalling that high values of \( S \), corresponding to higher background conductivities, represent a challenge for the numerical scheme, as the stiffness of the resistive magnetohydrodynamics equations becomes more severe. However, a higher resistivity jump between the background and the anomalous resistivity reproduces physical conditions where the plasma conductivity changes sharply over small distance scales, as expected in realistic conditions. The top panel of Fig. 6 shows that, when increasing the Lundquist number from \( S = 2.68 \times 10^5 \) to \( S = 2.68 \times 10^8 \), the asymptotic Lorentz factor reached by the plasmoid is smaller. The explanation of this effect is once
again to be found in the efficiency of magnetic energy conversion. When there is a higher conductivity jump between the central hot spot and the background, in fact, the fraction of magnetic energy that converts into thermal energy increases. This is shown in the middle panel of Fig. 6, which reports the time evolution of the specific internal energy of the plasma, which is higher for higher Lundquist numbers. The bottom panel of Fig. 6, on the other hand, shows the evolution of the reconnection rate $E_x/B_0$ (bottom panel) for models having the same magnetization $\sigma_m = 10.0$ but different Lundquist numbers.

This effect is reported in Fig. 7, showing the rest mass density in two models having different Lundquist numbers. No sign of instability is visible in simulations with Lundquist numbers as large as $S > S_c \sim 10^8$ (right panel). This instability, which resembles a tearing instability, was investigated through a linear analysis by Loureiro et al. (2007), and subsequently confirmed via numerical simulations in the Newtonian framework by Samtaney et al. (2009). Our results, combined with those by Loureiro et al. (2007), indicate that, in the transition to the relativistic regime, the critical Lundquist number increases from $S_c \sim 10^4$ to $S_c \sim 10^8$. Such a conclusion may have deep implications for high Lundquist number reconnection in relativistic astrophysical conditions, and it will deserve further investigations.

Finally, in a third series of simulations we have considered the effects of the full anisotropic Ohm law given by Eq. (20) with $\xi \neq 0$. In this case, a component of the magnetic field perpendicular to the $x-y$ plane must be introduced, otherwise the term $\vec{E} \cdot \vec{B}$ in (20) remains zero. Hence, we have investigated anisotropic effects in three spatial dimensions and in configurations with $B_z \neq 0$, the so-called “guide field” configurations (Lyubarsky 2005), for which we have chosen the value $B_z = 0.5B_0$. As a representative example, Fig. 8 shows the magnetic field $B^2$ on the slices $x = 0$ and $z = 0$ for the model $3D-m1.25-Bz0.5$ at time $t = 90$. The diffusion of the magnetic field is clearly visible in the region around the anomalous resistivity. It has to be remarked that, within our single fluid approximation, inertial resistivity effects like those encountered by Zenitani et al. (2009a) cannot be captured and are not discussed here. Simulations with the guide field configuration in combination with the anisotropic Ohm law turned out to be very challenging for the numerical scheme. In particular, strong magnetizations could not be reached and the results that we show here are limited to the case $\sigma_m \sim 1$. When discussing the effects introduced by an anisotropic Ohm law, we first need to distinguish them from those produced by the guide-field. By using a two-fluid approach, Zenitani et al. (2009a) concluded that the guide field modifies the composition of the output energy flux, which, as the guide field increases, changes from being enthalpy dominated to be Poynting dominated. Even within a single fluid approach, we confirm here a similar
This is shown in Fig. 9, where we compare the behavior of three different configurations each of which with an effective $\sigma_m = 1.25$. The solid red and the dashed blue line, in fact, refer, respectively, to a 3D simulation without the guide magnetic field and to a 3D simulation with the guide magnetic field, but with an otherwise isotropic Ohm law. In the case of a non zero guide field, the Lorentz factor is substantially smaller, while the decay of the magnetic energy, not reported here, is correspondingly slower. This is consistent with what reported by Zenitani et al. (2009a), who found that the introduction of the guide field has the net effect of diminishing the bulk kinetic energy. Having clarified this, we have increased the parameter $\xi$ to establish the extent to which results are affected by anisotropic Ohm law (green long-dashed line). The present implementation of the numerical scheme does not allow to treat the anisotropic parameter $\xi$ as a true free parameter, and we have therefore concentrated on a mildly anisotropic regime. When $\xi^2$ is increased from 0 (isotropic case) to 0.5, the Lorentz factor indeed grows, but by 1% only after $t = 100$. Intuitively, this effect can be explained in terms of the increased Lorentz force on the plasma, because of the extra current term on the right hand side of (21). More work is needed to analyze the anisotropic regime under more realistic conditions.

5 CONCLUSIONS

We have investigated the dynamics of High Lundquist number relativistic magnetic reconnection, by performing two dimensional and three dimensional magnetohydrodynamics simulations of a Petschek type configuration. By resorting to high order discontinuous Galerkin methods as proposed by Dumbser & Zanotti (2009), we have found that Lorentz factors up to $\sim 4$ can be obtained for plasma parameters $\sigma_m$ up to 20 in systems with Lundquist number $S \sim 10^5$. However, such values of the Lorentz factor decrease when $S$ is increased as a result of a reduced background resistivity. When $S$ is larger than a critical value $S_c \sim 10^8$, the Sweet-Parker layer becomes unstable, generating a chain of secondary magnetic islands. This effect deserves additional theoretical investigations, in view of the fact that a similar instability has already been reported in the Newtonian framework (Samtaney et al. 2009), but at much lower critical Lundquist numbers, i.e. for $S > S_c \sim 10^4$.

We have also shown that, when an anisotropic Ohm law is adopted, both the reconnection rate and the Lorentz factor of the accelerated plasmoid are slightly increased. Although this increase is small and within a few percent with respect to the isotropic Ohm law, strongly anisotropic regimes remain challenging even for our advanced numerical scheme. We plan to improve on these limitations in our future applications of relativistic magnetic reconnection to the curved spacetime around a neutron star, where an anisotropic Ohm law can play a substantial role.

Finally, it is worth mentioning that pure magnetohydrodynamics reconnection occurs in collisional plasmas, while the transition to collisionless reconnection is likely to enhance the reconnection rate (Uzdensky 2007; Uzdensky et al. 2010), and, presumably, also the acceleration properties. This possibility, which is related to some recent results of plasma physics (Hesse et al. 2007; Bessho & Bhattacharjee 2007), has been explored by Goodman & Uzdensky (2008) in accretion disc coronae and by McKinney & Uzdensky (2010) to trigger dissipation in Gamma-Ray Burst jets. The numerical exploration of collisionless reconnection has received less attention\(^3\) and it will represent another direction of our future analysis.

\(^3\) Also note that Lazarian et al. (2010), after solving numerically a reduced set of equations, showed that reconnection in a turbulent fluid occurs at a rate comparable to the rms velocity of the turbulence, irrespective of the degree of collisionality.

APPENDIX A: DERIVATION OF EQ. (21)

We first write the fluid four velocity, the magnetic field in the comoving frame and the electric field in the comoving frame as

\[ u^\nu = \Gamma(v^\nu + n^\nu) \quad (A1) \]

\[ e^\nu_{\mu} = F^{\mu\nu} u_\nu = \Gamma[n^\mu(\vec{v} \cdot \vec{E}) + E^\mu + (\vec{v} \times \vec{B})^\mu] \quad (A2) \]

\[ b^\nu = F^{\mu\nu} u_\mu = \Gamma[n^\mu(\vec{v} \cdot \vec{B}) + B^\mu - (\vec{v} \times \vec{E})^\mu] \quad (A3) \]

where we have used the definitions \( [3] \) and \( [4] \) for the electromagnetic tensor and where we have used the property \( \epsilon^{\mu\nu\lambda\sigma} = \epsilon^{\mu\sigma\lambda\nu} n_\kappa \). We then refer to the relation

\[ \sigma^{\mu\nu} = \sigma(q^\mu p^\nu + \xi^2 b^\mu b^\nu) \quad (A4) \]

and after noticing that \( b^\mu e_\mu = \vec{E} \cdot \vec{B} \) (it is a relativistic invariant) we rewrite \( [13] \) as

\[ I^\mu = q_0 \Gamma(v^\mu + n^\mu) + \sigma[\Gamma(\vec{v} \cdot \vec{E}) + E^\mu + (\vec{v} \times \vec{B})^\mu] + \sigma \xi^2 (\vec{v} \cdot \vec{E}) \Gamma(\vec{v} \cdot \vec{B}) + B^\mu - (\vec{v} \times \vec{E})^\mu] \quad . (A5) \]

At this point we compare \( [15] \) with \( I^\mu = \rho c n^\mu + J^\mu \) to find

\[ \rho_c = q_0 \Gamma + \sigma \Gamma(\vec{v} \cdot \vec{E}) + \sigma \xi^2 \Gamma(\vec{v} \cdot \vec{B}) \quad (A6) \]

\[ J^\mu = q_0 \Gamma v^\mu + \sigma E^\mu + \sigma \Gamma(\vec{v} \times \vec{B}) + \sigma \xi^2 (\vec{E} \cdot \vec{B}) \Gamma(B^\mu - (\vec{v} \times \vec{E})^\mu) \quad . (A7) \]
A last replacement of $q_0$ from (A6) into (A7) allows to derive (20) of the main text.
