(Dated: February 8, 2022)

An embedding of chaotic data into a suitable phase space creates a diffeomorphism of the original attractor with the reconstructed attractor. Although diffeomorphic, the original and reconstructed attractors may not be topologically equivalent. In a previous work we showed how the original and reconstructed attractors can differ when the original is three-dimensional and of genus-one type. In the present work we extend this result to three-dimensional attractors of arbitrary genus. This result describes symmetries exhibited by the Lorenz attractor and its reconstructions.

I. INTRODUCTION

Mappings of scalar and vector time series into suitable phase spaces are regularly used to visualize processes that generate experimental data [1, 2]. When the mapping is an embedding, a diffeomorphism exists between the original ("experimental") attractor and the reconstructed attractor. It is known from numerous examples that a single time series can be embedded into a phase space in several different ways, giving rise to reconstructed attractors that are diffeomorphic but not topologically equivalent [3, 4, 5]. By topologically equivalent (isotopic) we mean that there is a smooth transformation (isotopy), or change of coordinates, that deforms one into the other [6]. If there is no smooth transformation that deforms one into the other, the two are topologically inequivalent. As a particular example of topologically inequivalent attractors that are related by a diffeomorphism restricted to the attracting set, we cite the Lorenz attractor [7]. Under the vector embedding $(x(t), y(t), z(t)) \rightarrow \mathbb{R}^3$ the attractor exhibits rotation symmetry around the $z$-axis, but under the scalar differential embedding $(x(t), \dot{x}(t), \ddot{x}(t)) \rightarrow \mathbb{R}^3$ the reconstructed attractor exhibits inversion symmetry through the origin [3, 4, 8, 9]. The attractors with two different order-2 symmetries cannot be smoothly deformed into each other in $\mathbb{R}^3$. Representations of these two attractors by their branched manifolds are shown in Fig. 1. It is also known that diffeomorphic but topologically inequivalent embeddings can result from time delay embeddings with different delays [10].

This raises an important question. How much of what we learn by studying a reconstructed attractor depends on the embedding and how much is independent of the embedding? The properties that are independent of the embedding characterize the original attractor.

Geometric properties, such as the spectrum of fractal dimensions, are in principle diffeomorphism independent [10] (but see [11]). Dynamical properties, such as the spectrum of Lyapunov exponents, are also diffeomorphism independent (but see [12, 13]). As a result, these real numbers can usually be assumed to be valid for the original attractor when computed from any reconstructed attractor. Conversely, they cannot be used to distinguish one embedding from another. Nor do these real numbers shed any light on the mechanism generating chaotic behavior [14].

Topological indices shed a great deal of light on the mechanism generating chaotic behavior [2, 4, 15]. At the same time they are not embedding invariants. As a result we must understand what part of the topological information obtained from a reconstructed attractor is independent of the embedding, and what part is not. This program has been completed for three dimensional attractors that are contained in a bounding torus of genus one [14]. In this case we find that embeddings have three degrees of freedom: parity, global torsion, and knot type.

In the present work we extend these results to three-dimensional attractors of higher genus $(g > 1)$. These include many attractors generated by autonomous dynamical systems with two-fold or higher-fold symmetry [4, 16, 17, 18]. We find the analogs of parity and global torsion, but do not discuss knot type, but all embeddings reveal the same stretching and folding mechanism.

Our work is restricted to three-dimensional attractors. These are attractors that exist in a three-dimensional manifold, not necessarily $\mathbb{R}^3$. This restriction is nec-
necessary because the topological indices that we compute (linking numbers, relative rotation rates) are for closed periodic orbits that have a rigid organization in three-dimensional manifolds \([6, 15]\).

In Sec. II we briefly review the results for the genus-one case. In Sec. III we construct the analog in the higher-genus case, for global torsion in the genus-one case. In Sec. IV we construct the analog, in the higher genus-case, of parity in the genus-one case. We discuss the implications of our results in Sec. V.

II. REVIEW OF GENUS-ONE RESULTS

In [14] we assumed that an experimental attractor is contained in a three-dimensional manifold that has the global topology of a genus-one torus. An embedding constructs a diffeomorphism between the original and reconstructed attractors. A different embedding provides another diffeomorphism between the original and another reconstructed attractor. The two (in fact, all) reconstructed attractors are diffeomorphic when restricted to the attracting set. The question of how embeddings of an unseen attractor can differ simplifies to the question of how diffeomorphisms of a torus to a torus can differ.

Diffeomorphisms form a group. The subset of diffeomorphisms that is isotopic to the identity forms an invariant subgroup \([6, 14]\). In fact, this invariant subgroup cannot change any topological indices, which are integers or rational fractions \([3, 15]\). The quotient group, diffeomorphisms/(diffeomorphisms isotopic to identity), is discrete and describes the equivalence classes of diffeomorphisms of the torus \([6, 14]\). Each element in this discrete group changes the topological indices in a different way.

The action of this discrete group can be understood by its action on the boundary of the torus \([6, 14]\). This is done as follows. Cut the torus open and stretch it out along the central axis. Label the position along the axis by an angle \(\phi\), \(0 \leq \phi \leq 2\pi\). Choose a plane at \(\phi\) and rotate the intersection of the torus boundary with this plane by an angle \(\theta\). Set \(\theta(\phi = 0) = 0\). Now close the torus back up. A diffeomorphism is created by this process only when periodic boundary conditions are satisfied, so that \(\theta(\phi = 2\pi) = 2\pi n\), with \(n\) an integer \([19]\). This integer is the degree of freedom called global torsion \([3, 14, 20]\).

A parity transformation is obtained by reflecting the torus in an external mirror. Parity is a single index: \(P = \pm 1\).

A genus-one torus can be embedded into \(R^3\) by allowing its central axis to follow the curve of any knot. We do not yet know how to classify knots algebraically. Even less is known about extrinsic embeddings of higher genus tori in \(R^3\). We do not discuss extrinsic embeddings of genus-\(g\) tori \((g > 1)\) into \(R^3\) in the present work.

III. ANALOG OF GLOBAL TORSION

A bounding torus of genus \(g\) \([21, 22]\) can be constructed, Lego© fashion, from \(Y\)-junctions. These are two-dimensional manifolds with three ports. For our purposes there are two types: splitting units with one input port and two output ports and joining units with two input ports and one output port. These units are shown in Fig. 2(a) and Fig. 2(b). A canonical bounding torus of genus three is shown in Fig. 3. The Lorenz attractor is contained in a bounding torus of this type. The figure shows how this bounding torus is decomposed into two input units and two output units. As usual, output ports connect to input ports, and there are no free ends \([3, 15, 23, 24]\).

In Fig. 3(b) we insert a “flow tube” between each output port and the input port on a different unit that it is connected to. Periodic boundary conditions are satisfied if each of these tubes is rotated through an integer number of full twists \([14, 19]\). Since there are \(4 = 2(3 - 1)\) units in the decomposition of the genus-three torus, each has three ports, and one tube is inserted between each pair of ports; there is a total of \((3 - 1) \times 3\) tubes, each of which can exhibit an integer twist. Each configuration is diffeomorphic but not isotopic to every other.

The general result is that a genus-\(g\) torus can be decomposed into \(g - 1\) splitting units and \(g - 1\) joining units, so that \(2(g - 1) \times (3/2) = 3(g - 1)\) tubes can be inserted. As a result, the genus-\(g\) analog of the genus-1 global torsion is an index \(Z^N\), \(N = 3(g - 1)\). This is a set of \(N = 3(g - 1)\) integers, one for each inserted flow tube. Recall that for bounding tori, \(g = 1\) or \(g \geq 3\) \([21, 22]\).

In [14] we assumed that an experimental attractor is contained in a three-dimensional manifold that has the global topology of a genus-one torus. An embedding constructs a diffeomorphism between the original and reconstructed attractors. A different embedding provides another diffeomorphism between the original and another reconstructed attractor. The two (in fact, all) reconstructed attractors are diffeomorphic when restricted to the attracting set. The question of how embeddings of an unseen attractor can differ simplifies to the question of how diffeomorphisms of a torus to a torus can differ.

Diffeomorphisms form a group. The subset of diffeomorphisms that is isotopic to the identity forms an invariant subgroup \([6, 14]\). In fact, this invariant subgroup cannot change any topological indices, which are integers or rational fractions \([3, 15]\). The quotient group, diffeomorphisms/(diffeomorphisms isotopic to identity), is discrete and describes the equivalence classes of diffeomorphisms of the torus \([6, 14]\). Each element in this discrete group changes the topological indices in a different way.

The action of this discrete group can be understood by its action on the boundary of the torus \([6, 14]\). This is done as follows. Cut the torus open and stretch it out along the central axis. Label the position along the axis by an angle \(\phi\), \(0 \leq \phi \leq 2\pi\). Choose a plane at \(\phi\) and rotate the intersection of the torus boundary with this plane by an angle \(\theta\). Set \(\theta(\phi = 0) = 0\). Now close the torus back up. A diffeomorphism is created by this process only when periodic boundary conditions are satisfied, so that \(\theta(\phi = 2\pi) = 2\pi n\), with \(n\) an integer \([19]\). This integer is the degree of freedom called global torsion \([3, 14, 20]\).

A parity transformation is obtained by reflecting the torus in an external mirror. Parity is a single index: \(P = \pm 1\).

A genus-one torus can be embedded into \(R^3\) by allowing its central axis to follow the curve of any knot. We do not yet know how to classify knots algebraically. Even less is known about extrinsic embeddings of higher genus tori in \(R^3\). We do not discuss extrinsic embeddings of genus-\(g\) tori \((g > 1)\) into \(R^3\) in the present work.

III. ANALOG OF GLOBAL TORSION

A bounding torus of genus \(g\) \([21, 22]\) can be constructed, Lego© fashion, from \(Y\)-junctions. These are two-dimensional manifolds with three ports. For our purposes there are two types: splitting units with one input port and two output ports and joining units with two input ports and one output port. These units are shown in Fig. 2(a) and Fig. 2(b). A canonical bounding torus of genus three is shown in Fig. 3. The Lorenz attractor is contained in a bounding torus of this type. The figure shows how this bounding torus is decomposed into two input units and two output units. As usual, output ports connect to input ports, and there are no free ends \([3, 15, 23, 24]\).

In Fig. 3(b) we insert a “flow tube” between each output port and the input port on a different unit that it is connected to. Periodic boundary conditions are satisfied if each of these tubes is rotated through an integer number of full twists \([14, 19]\). Since there are \(4 = 2(3 - 1)\) units in the decomposition of the genus-three torus, each has three ports, and one tube is inserted between each pair of ports; there is a total of \((3 - 1) \times 3\) tubes, each of which can exhibit an integer twist. Each configuration is diffeomorphic but not isotopic to every other.

The general result is that a genus-\(g\) torus can be decomposed into \(g - 1\) splitting units and \(g - 1\) joining units, so that \(2(g - 1) \times (3/2) = 3(g - 1)\) tubes can be inserted. As a result, the genus-\(g\) analog of the genus-1 global torsion is an index \(Z^N\), \(N = 3(g - 1)\). This is a set of \(N = 3(g - 1)\) integers, one for each inserted flow tube. Recall that for bounding tori, \(g = 1\) or \(g \geq 3\) \([21, 22]\).

A parity transformation is obtained by reflecting the torus in an external mirror. Parity is a single index: \(P = \pm 1\).

A genus-one torus can be embedded into \(R^3\) by allowing its central axis to follow the curve of any knot. We do not yet know how to classify knots algebraically. Even less is known about extrinsic embeddings of higher genus tori in \(R^3\). We do not discuss extrinsic embeddings of genus-\(g\) tori \((g > 1)\) into \(R^3\) in the present work.

IV. LOCAL REFLECTIONS

The genus-\(g\) analog of the parity transformation in the genus-1 case consists of local reflections.

The construction of local reflections is subtle. It is clear what a local reflection does to a branched manifold that describes a genus-\(g\) flow. It simply maps a joining unit of a branched manifold into its mirror image. This is illustrated in Fig. 4. The problem is that local reflections in \(R^3\) cannot be used in general to create diffeomorphisms.
between the two flows responsible for the branched manifolds related by a local reflection, as shown in Fig. 1.

We can create diffeomorphisms that include local reflections as shown in Fig. 3. Choose a joining unit and insert a flow tube of length $L$ at each port. Each flow tube contains a branch of the branched manifold describing the attractor generated by the flow. Deform the flow so that it is “laminar” or “uniform” in each flow tube. By “laminar” or “uniform” we mean the flow assumes the form $\dot{x} = \text{const.}$, $\dot{y} = 0$, $\dot{z} = 0$ in local coordinates. Here $x$ is a coordinate along the central axis of the cylindrical flow tube, $y$ is a coordinate in the plane of the branch through the flow tube, and $z$ measures distance above or below this plane. The branch occurs in the plane $z = 0$.

Now embed the three dimensional flow into $R^4$ by introducing a fourth coordinate, $w$. The original three dimensional flow has coordinates $(x(t), y(t), z(t), w)$ with $w = 0$. Now create a diffeomorphism between this flow in a three-dimensional manifold in $R^4$, $R^3 \subset R^4$, and another three-dimensional manifold in $R^4$, $M^3 \subset R^4$, as follows. Perform a rotation through $\pi$ radians in the $z, w$ plane in each flow tube according to $(z, 0) \rightarrow (\cos(x/L), \sin(x/L))$. This rotation maps coordinate $(y, z)$ at the input side of a flow tube $(x = 0)$ to coordinate $(y, -z)$ at the output side $(x = L)$. In the joining unit, map coordinates $(x, y, z)$ to their mirror images $(x, y, -z)$ in the $z = 0$ plane. This set of transformations creates a diffeomorphism between flows in $R^4$ and $M^3$. The projection of the branched manifold describing the flow in $M^3$ into $R^3$ differs from the branched manifold describing the flow in $R^3$ by the mirror image of the joining unit, as shown in Fig. 1. The two branched manifolds are 1-1, locally isomorphic, and not isotopic (i.e., globally distinct). The flows in $R^3$ and $M^3$ are diffeomorphic but the projection of the flow in $M^3 \subset R^4$ into $R^3$ is not an embedding. This phenomenon has already been encountered in descriptions of autonomous coupled dynamo systems [25].

Local reflections can be carried out independently on each of the $g - 1$ joining units. The effect of a local reflection can be seen by comparing the two representations of the Lorenz flow shown in Fig. 1. A local reflection has already been carried out on a joining unit in Fig. 1(b). This operation transforms a rotation-symmetric representation of the attractor (Fig. 1(a)) to an inversion-symmetric representation of the attractor (Fig. 1(b)). We can describe the two representations shown in Fig. 1 as $(+, +)$ and $(-, +)$, with the positions referring to the joining units on the left and right, and the signs referring to a reflection ($-$) or no reflection ($+$). Two other representations are easily constructed with signatures $(-, -)$ and $(+, -)$. The latter two are related to the former two by a global reflection transformation.

A strange attractor in a genus-$g$ torus has $2^{(g-1)}$ representations related by local reflections. They are all related to each other by diffeomorphisms acting in $R^4$. None is isotopic to any other.
V. SUMMARY

Embeddings based on scalar or vector time series create diffeomorphisms between the original attractor and the reconstructed attractor. Different embeddings create diffeomorphic reconstructed attractors that are not necessarily topologically equivalent - that is, not isotopic. Since topology indicates clearly what are the mechanisms (stretching, folding, tearing, squeezing) that generate complex behavior [12], it is an important question to ask: How much do we learn about the original attractor by carrying out a topological analysis of a reconstructed attractor, and how much about the embedding do we learn? For the genus-one case the result is that embeddings can differ by three degrees of freedom: parity, global torsion, and knot type. The mechanism displayed is independent of the embedding [14].

In this work we have answered this question for attractors contained in higher-genus bounding tori. We have done this by constructing a discrete classification of all nonisotopic (topologically inequivalent) diffeomorphisms of a bounding torus into itself. We have enumerated the degrees of freedom, not including how the bounding torus of a bounding torus into itself. We have done this by constructing a discrete classification of all nonisotopic (topologically inequivalent) diffeomorphisms between the original attractor and the reconstructed attractor. Different embeddings create diffeomorphic reconstructed attractors that are not necessarily topologically equivalent - that is, not isotopic. Since topology indicates clearly what are the mechanisms (stretching, folding, tearing, squeezing) that generate complex behavior [12], it is an important question to ask: How much do we learn about the original attractor by carrying out a topological analysis of a reconstructed attractor, and how much about the embedding do we learn? For the genus-one case the result is that embeddings can differ by three degrees of freedom: parity, global torsion, and knot type. The mechanism displayed is independent of the embedding [14].

In this work we have answered this question for attractors contained in higher-genus bounding tori. We have done this by constructing a discrete classification of all nonisotopic (topologically inequivalent) diffeomorphisms of a bounding torus into itself. We have enumerated the degrees of freedom, not including how the bounding torus can be embedded into \( \mathbb{R}^3 \). There are two degrees of freedom: local torsion in each of \( 3(g - 1) \) flow tubes and local reflections in each of \( g - 1 \) joining units. It is useful to regard these degrees of freedom as follows: There are \( 2^{(g - 1)} \) topologically inequivalent representations of an attractor related to each other by different subsets of local reflection transformations. Each is the patriarch for a \( 3(g - 1) \) parameter family of strange attractors defined by an index \( Z^{3(g - 1)} [19] \). All representations are topologically inequivalent.

What is an invariant of an embedding, and the same for each of the \( 2^{(g - 1)} \otimes Z^{3(g - 1)} \) representatives of a strange attractor is the mechanism that generates the dynamics. The mechanism describes how the flow is split apart to flow to different regions of the phase space, and how different parts of the phase space are joined [3, 14]. This information is encoded in the transition matrix: stretching is described by the rows of this matrix and squeezing by the columns of this matrix [21, 22].
