Abstract

We consider the Liénard equation and we give a sufficient condition to ensure existence and uniqueness of limit cycles. We compare our result with some other existing ones and we give some applications.

Key words: Liénard equation, limit cycles, existence and uniqueness

1 Introduction

In this paper we consider the Liénard equation:

\[ \ddot{x} + f(x)\dot{x} + g(x) = 0, \tag{1} \]

where \( f, g : \mathbb{R} \to \mathbb{R} \), with particular attention to the existence and uniqueness of limit cycles. This is a classical problem of non–linear oscillation for second order differential equations. Different assumptions on \( f \) and \( g \) and different methods used to study the problem, gave rise to a large amount of literature on this topic; for a review of results and methods, reader can consult [7], Chapter IV of the book [13] or [12]. In the following we will give some more references.

We make the following assumptions on \( f \) and \( g \):

(A) \( f \) is a continuous function and \( g \) verifies a locally Lipschitz condition;
(B) \( f(0) < 0, f(x) > 0 \) for \( |x| > \delta \), for some \( \delta > 0 \), and \( xg(x) > 0 \) for \( x \neq 0 \).

\ast Corresponding author.

Email addresses: t.carletti@sns.it (Timoteo Carletti), villari@math.unifi.it (Gabriele Villari).
For the Liénard equation condition (A) assures existence and uniqueness of the Cauchy initial value problem, in fact passing to the Liénard plane the second order differential equation is equivalent to the following first order system:

\[
\begin{align*}
\dot{x} &= y - F(x) \\
\dot{y} &= -g(x),
\end{align*}
\]

where \( F(x) = \int_0^x f(\xi) \, d\xi \). Hence assuming hypothesis (A) the right hand side of (2) is Lipschitz continuous, from which the claim follows.

Assumption (B) guarantees that the origin is the only singular point of the system, which results a repellor, moreover orbits of (2) turn clockwise around it. Hypothesis on the sign of \( f(0) \) can be weakened by asking \( x F(x) < 0 \) for \( |x| \) small, we nevertheless prefer the former formulation (A) because of the applications we will give in the last part of the paper.

Assuming assumptions (A) and (B) on \( f \) and \( g \), our main result will be the following

**Theorem 1.1** Let \( G(x) = \int_0^x g(\xi) \, d\xi \) and suppose that \( F \) and \( G \) verify:

- \( (C) \) \( F \) has only three real transversal zeros, located at \( x_0 = 0, x_2 < 0 < x_1 \). Assume moreover that \( F \) is monotone increasing outside the interval \([x_2, x_1]\);
- \( (D) \) \( G(x_1) = G(x_2) \);
- \( (E) \) \( \limsup_{x \to +\infty} [G(x) + F(x)] = +\infty \) and \( \limsup_{x \to -\infty} [G(x) - F(x)] = +\infty \).

Then system (2) has a unique periodic orbit in the \((x, y)\)-plane which is stable.

Because of the equivalence of equation (1) and system (2) also the former has a unique limit cycle if Theorem applies.

We postpone the proof of the Theorem to the next section, in the following we will discuss the role of our hypotheses and compare this result with other existence and uniqueness results concerning Linénard systems.

Our result follows from investigating the geometry of limit cycles, in particular their (eventual) intersections with the lines \( x = x_1 \) and \( x = x_2 \). With Proposition 2.1 we give sufficient conditions to ensure intersection of limit cycles with one or both lines \( x = x_1 \) and \( x = x_2 \). Our result will then follow joining these informations with the result of Theorem 1 [9].

First of all we stress that assumptions are quite standard ones. Hypotheses (A), (B), (C) and (E) guarantee existence of limit cycles as it will be shown in § 2.1. Hypotheses on \( F \) and the equality for \( G \) at roots of \( F(x) = 0 \) are fundamental for our proof. While we can already find in literature such hypotheses of \( F \), the link between zeros of \( F \) and values of \( G \) at these points are new, as far as
we know. We remark that hypothesis (C) can be weakened by allowing $F$ to have zeros inside $(x_2, x_1)$, other than $x_0 = 0$, where it doesn’t change sign.

We already gave some bibliography of results concerning existence and/or uniqueness of limit cycles for Liénard equations; we don’t try to compare our result with all the existing ones, we will restrict ourselves to emphasize the strong point of our Theorem and to compare it with some general results.

First of all we don’t assume any parity conditions on $F$ and/or $g$, on the contrary if $F$ and $g$ are odd, then Theorem 1.1 contains the Levinson–Smith result [3] as particular case: let $x_1 = -x_2$ be the non–zeros root of $F(x) = 0$, $G(x)$ is even because of oddness of $g$, and then $G(x_1) = G(-x_2)$.

The monotonicity on $F$ is required only outside the interval determined by the smallest and largest zeros, namely its derivative $F'(x) = f(x)$ can have several zeros inside this interval, this is a more general situation than the results of Massera [4] and Sansone [5]. The last one follows from our result by remarking that if $g(x) = x$, then $G(x) = x^2/2$ and let $\Delta > 0$ be such that $F(\Delta) = F(-\Delta) = 0$, we get $G(\Delta) = G(-\Delta)$.

The second remark concerns the hypothesis (D): it’s easy to verify if this condition on $G$ holds, just compare the function at two points. We don’t need to use the inversion of any function as in the Filippov case [1] (and in all results inspired by his method), or to impose conditions on functions obtained by composition and inversion. These facts make our Theorem easily applicable as results of section 3 will show.

2 Main result

The aim of this section is to prove our main result, Theorem 1.1. The proof is divided in two steps, presented in § 2.2 and § 2.3. Before let us introduce two preliminary results, first, Proposition 2.1, whose role is to give information about the geometry of limit cycles w.r.t. lines $x = x_i$, where $x_i$ are non zero roots of $F(x) = 0$. Second, give a proof (§ 2.1) of existence of limit cycles assuming hypotheses (A), (B), (C) and (E), as claimed in the introduction.

**Proposition 2.1** Let $f$ and $g$ verify hypotheses (A) and (B). Let $F(x) = \int_0^x f(\xi) \, d\xi$, $G(x) = \int_0^x g(\xi) \, d\xi$ and assume $F(x)$ verify hypothesis (C). Then

- if $G(x_1) \geq G(x_2)$ all (eventual) limit cycles of (2) will intersect the line $x = x_2$;
- whereas if $G(x_1) \leq G(x_2)$ all (eventual) limit cycles of (2) will intersect the line $x = x_1$. 

Proof. Let us denote by $X_L(x, y) = (y - F(x), -g(x))$ the Liénard field associated to (2) and let us consider the family of ovals given by: $\mathcal{E}_N = \{(x, y) \in \mathbb{R}^2 : y^2/2 + G(x) - N = 0\}$.

Let us consider the case $G(x_1) \geq G(x_2)$, the other can be handle similarly and we will omit it. The oval $\mathcal{E}_{G(x_2)}$ doesn’t intersect the line $x = x_1$, whereas $\mathcal{E}_{G(x_1)}$ passes through points $\left(x_2, \pm \sqrt{2(G(x_1) - G(x_2))}\right)$. Namely $\mathcal{E}_{G(x_1)}$ contains in its interior $\mathcal{E}_{G(x_2)}$ which contains the origin in its interior.

The flow of Liénard system (2) is transversal to $\mathcal{E}_{G(x_2)}$ (more precisely it points outward w.r.t to $\mathcal{E}_{G(x_2)}$):

$$< \nabla \mathcal{E}_{G(x_2)}, X_L(x, y) \bigg|_{\mathcal{E}_{G(x_2)}} > = -F(x)g(x) \geq 0,$$

equality holds only for $x = 0$ and $x = x_2$. Let us call $(x_1^*, 0)$ the unique intersection point of $\mathcal{E}_{G(x_2)}$ with the positive $x$–axis.

Hence from Poincaré–Bendixson Theorem no limit cycle can be completely contained in the strip $[x_2, x_1^*] \times \mathbb{R}$, moreover orbits of (2) spiral outward leaving $\mathcal{E}_{G(x_2)}$. Thus any (eventual) limit cycle must intersect the line $x = x_2$. \qed

2.1 Existence of limit cycles

Let us investigate the existence of limit cycles. Consider assumption (E), if $\lim_{x \to \pm \infty} G(x) = +\infty$, we observe that assumption (C) guarantees that exists $\epsilon > 0$ and $\alpha < 0 < \beta$ such that $\int_{\alpha}^{\beta} f(\xi) \, d\xi > \epsilon$. Moreover $f(x) > 0$ for $x \not\in [\alpha, \beta]$. We can then apply Theorem 1 of [8] to obtain existence of limit cycles.

On the other hand, let us assume $\lim_{x \to +\infty} G(x) < +\infty$ (the case $\lim_{x \to -\infty} G(x) < +\infty$ can be handle similarly and we omit it), then using Theorem 3 of [10] we complete the proof of the existence of limit cycles.

2.2 Uniqueness: Step I

In [9] the following result has been proved

**Theorem 2.2** Let $f$ and $g$ verify hypotheses (A), (B) and let $F$ verify hypothesis (C). Let $x_2 < 0 < x_1$ be the non–zero roots of $F(x) = 0$. Assume that all limit cycles of (2) intersect the lines $x = x_2$ and $x = x_1$. Then system (2) has at most one limit cycle, if it exists it is stable.
Let us give by completeness its proof.

**Proof.** We claim that for any limit cycle, \( \gamma \), of system (2) we have:

\[
\oint_{\gamma} g(x) \, dt = 0, \quad \oint_{\gamma} g(x)y \, dt = 0 \quad \text{and} \quad \oint_{\gamma} g(x) \left[ y - F(x) \right] \, dt = 0;
\]

this can be proved easily by remarking that \( g(x)y = \frac{d}{dt} \left( \frac{1}{2} y^2 \right) \). Hence:

\[
\oint_{\gamma} g(x)F(x) \, dt = 0. \tag{3}
\]

Hypotheses (B) and (C) give \( F(x)g(x) < 0 \) for all \( x \in (x_2, 0) \cup (0, x_1) \), then using the monotonicity of \( F \) outside \([x_2, x_1]\) and the hypothesis that all limit cycles intersect both line \( x = x_1 \) and \( x = x_2 \), we claim that if \( \gamma_1 \) and \( \gamma_2 \) are two limit cycles of (2), \( \gamma_1 \) contained in the interior of \( \gamma_2 \), one has:

\[
\oint_{\gamma_1} g(x)F(x) \, dt < \oint_{\gamma_2} g(x)F(x) \, dt,
\]

which contradicts (3) and so the number of limit cycles is at most one. \( \square \)

The weak point of this result is the assumption that all limit cycles must intersect both lines \( x = x_1 \) and \( x = x_2 \), in general this is not true and moreover it can be difficult to verify. With our result we give sufficient hypotheses to ensure this fact. Our Theorem is based on a slightly generalization of Theorem 2.2 that we state here without proof, which can be obtained following closely the previous one.

**Theorem 2.3** Assume (A), (B) and (C) of Theorem 1.1 hold, let \( N_{x_1,x_2} \) denote the number of limit cycles of system (2) which intersect both lines \( x = x_i \), \( i = 1, 2 \). Then \( N_{x_1,x_2} \leq 1 \).

We are now able to prove the main part of our result.

### 2.3 Uniqueness: Step II

The number of limit cycles of system (2) is by definition \( N_{l.c.} = N_{x_1,x_2} + N_{x_1} + N_{x_2} \), being \( N_x \) the number of limit cycles which intersect only the line \( x = x_i \). So to prove our main result we only need to control \( N_{x_i} \).

From Proposition 2.1 and assumption (D) we know that all limit cycles must intersect both lines \( x = x_i \), \( i = 1, 2 \). Namely \( N_{x_i} = 0 \), \( i = 1, 2 \).

As already remarked in § 2.1 our hypotheses imply existence of at least one limit cycle, \( N_{l.c.} \geq 1 \), thus we finish our proof recalling that Theorem 2.3 gives \( N_{l.c.} \leq 1 \).
Before passing to the applications of our Theorem, let us consider in the next paragraph what can happen when we do not assume hypothesis (D).

2.4 Removing the assumption $G(x_1) = G(x_2)$

The first remark is that assumption (D) cannot be removed without avoiding cases with more than one limit cycle, as the following example shows.

**Remark 2.4 (A case with $G(x_1) < G(x_2)$)** Starting from a classical counterexample of Duff and Levinson [2] to the H. Serbin conjecture [6], we exhibit a polynomial system where all hypotheses (A)–(E) are verified but (D), which has 3 limit cycles.

Let us consider the equation:

$$\ddot{x} + \epsilon f(x) \dot{x} + g(x) = 0, \quad (4)$$

where $\epsilon$ is a small parameter, $g(x) = x$ and $f$ is a polynomial of degree 6, $f(x) = \sum_{i=0}^{3} a_{2i}x^{2i} + Ax + Bx^3$, where $a_6I_0 = -4/81$, $a_2I_2 = 49/81$, $a_4I_4 = -14/9$, $a_6I_6 = 1$, $I_{2k} = \int_{0}^{2\pi} \sin^2 \theta \cos^{2k} \theta d\theta$ and $A, B$ to be determined. Coefficients $(a_{2i})_0$ are fixed in such a way that, passing to polar coordinates, for $\epsilon$ small enough and $A, B = 0$, system (4) has three limit cycles.

In fact let us introduce polar coordinates: $x = r \cos \theta$, $y = r \sin \theta$, then (4) can be rewritten as:

$$\begin{cases}
\dot{x} = y \\
\dot{y} = -g(x) - \epsilon f(x)y
\end{cases},$$

thus:

$$\frac{dr}{d\theta} = \frac{\epsilon rf(r \cos \theta) \sin^2 \theta}{1 + \epsilon rf(r \cos \theta) \sin \theta \cos \theta}.$$  

If $r$ and $|\epsilon|$ are small enough, we can rewrite the previous equation as:

$$\frac{dr}{d\theta} = \epsilon \left[H_0(r, \theta) + \epsilon H_1(r, \theta) + \epsilon^2 H_2(r, \theta, \epsilon)\right], \quad (5)$$

where $H_i$ are analytic functions of $r, \theta$ and $\epsilon$. Let $\rho > 0$ and let us denote by $r(\theta, \rho, \epsilon)$, the solution of (5) with initial datum $r = \rho$, then our system has a limit cycle if and only if $\rho$ is an isolated positive root of $r(2\pi, \rho, \epsilon) - \rho = 0$. Integrating (5) we get:

$$r(2\pi, \rho, \epsilon) - \rho = \epsilon \tilde{F}(\rho) + \epsilon^2 R_2(\rho, \epsilon), \quad (6)$$

where $\tilde{F}(\rho) = \int_{0}^{2\pi} \rho f(\rho \cos \theta) \sin^2 \theta d\theta$ and $R_2(\rho, \epsilon)$ is some analytic remainder function. With our choice of $(a_{2i})_{0 \leq i \leq 3}$ we obtain: $\tilde{F}(\rho) = \rho(\rho^2 - 1/9)(\rho^2 - 4/9)(\rho^2 - 1)$, and then from (6) we conclude that if $|\epsilon|$ is sufficiently small,
$r(2\pi, \rho, \epsilon) - \rho$ has three positive isolated simple roots, $\epsilon$-close to $1/3$, $2/3$ and $1$.

The method used to find the number of limit cycle doesn’t involve the values of $A, B$, we claim that we can vary these parameters in such a way $F(x) = \int_0^x f(\xi) \, d\xi$ verifies hypothesis (C), with $|x_2| > x_1$ and then $G(x) = x^2/2$ doesn’t verify hypothesis (D). Just as an example consider:

$$F(x) = \frac{x}{\pi} \left( -\frac{4}{81} + \frac{196}{81} x^2 - \frac{112}{9} x^4 + \frac{64}{5} x^6 + \frac{1}{200} x + \frac{1}{2} x^3 \right),$$

which has three real zeros $x_0 = 0$, $x_2 < 0 < x_1$ and its monotone increasing outside $(x_2, x_1)$. Moreover $f(x) = F'(x)$ has four zeros in the same interval $^1$.

To conclude this part let us remark that adding further assumptions on $F(x)$, one can ensure that all limit cycles must intersect both lines $x = x_1$, $x = x_2$, thus obtaining a existence and uniqueness result for (2). For instance one can prove the following

**Theorem 2.5** Assume $f$ and $g$ verify hypotheses (A) and (B). Let $F$ and $G$ be the primitives of $f$ and $g$ vanishing at $x = 0$ and assume they verify hypotheses (C) and (E). Assume one of the following conditions hold:

- $(D')$ $G(x_1) > G(x_2)$ and there exists $x_2^* \in (x_2, 0)$ such that $F(x_2^*) \geq \sqrt{2G(x_1)}$;
- $(D'')$ $G(x_1) < G(x_2)$ and there exists $x_1^* \in (0, x_1)$ such that $F(x_1^*) \leq -\sqrt{2G(x_2)}$.

Then Liénard system (2) has one and only one limit cycle.

**Proof.** We only prove the previous Theorem assuming $(D')$, being the other case very similar. Let us assume $G(x_1) > G(x_2)$ and that there exists $x_2^* \in (x_2, 0)$ such that $F(x_2^*) \geq \sqrt{2G(x_1)}$, we will prove that any orbit which intersects the line $x = x_2^*$ must intersect also the line $x = x_1$.

Considering the oval $\mathcal{E}_{G(x_1)} = \{(x, y) \in \mathbb{R}^2 : y^2/2 + G(x) - G(x_1) = 0\}$ one realizes that there exists a unique point $(0, y_A)$ with $y_A < \sqrt{2G(x_1)}$, whose future orbit will intersect the line $x = x_1$ at the point $(x_1, 0)$.

Let us consider now a point $(x_2^*, y_B)$, with $y_B \geq F(x_2^*)$, we claim that its future orbit will intersect the $y$–axis at some $(0, y_{B'})$ such that $y_{B'} > \sqrt{2G(x_1)}$. This can be proved by considering the evolution of the function $\Lambda(x, y) = y^2/2 + G(x)$ under the flow of the Liénard system.

$^1$ Using Sturm’s method to find real roots of polynomials we obtain that the zeros of $F$ belong to the intervals: $x_2 \in [-1.130, -1.129]$ and $x_1 \in [0.247, 0.248]$, whereas zeros of $f$ verify: $x_1' \in [-0.969, -0.9688], x_3' \in [-0.343, -0.342], x_2' \in [-0.173, -0.172]$ and $x_3' \in [0.139, 0.140]$.
Summarizing the orbit of all point of the form \((x_2^*, y_B)\) such that \(y_B > F(x_2^*)\), will intersect the line \(x = x_1\) with positive \(y\) coordinate. This conclude the proof once we remark that orbits of points \((x_2^*, y')\) such that \(y' < F(x_2^*)\), turn clockwise and will intersect again the line \(x = x_2^*\) at some point \((x_2^*, y'')\) with \(y'' \geq F(x_2^*)\).

To complete the proof of the Theorem one remark that by Proposition 2.1 all limit cycles must intersect the line \(x = x_2\), hence they must intersect the line \(x = x_2^*\), being \(x_2 < x_2^*\). By the first part these limit cycles intersect also the line \(x = x_1\) and then applying Theorem 2.2 we conclude the proof. \(\Box\)

3 Some applications

In this section we give some applications of Theorem 1.1. The first application concerns Liénard’s systems (2), where \(F\) and \(G\) verify all hypotheses of Theorem 1.1 but (D) (§ 3.1 and § 3.2). Our aim is to show that we can find a new Liénard system (slightly modified version of the original one) for which Theorem 1.1 holds, then exhibiting one and only a limit cycle. The second application is of different nature, starting with a given Liénard system, which doesn’t verify assumptions of Theorem 1.1, we prove existence and uniqueness of limit cycles for a new system obtained from the first one just by introducing two parameters. We will consider the polynomial case (§ 3.3) and a more general one (§ 3.4).

3.1 Case I: deform \(g\)

Let us recall that \(F\) has three real zeros, \(x_0 = 0\) and \(x_2 < 0 < x_1\), let us assume \(G(x_1) \neq G(x_2)\). Let us introduce the 1–parameter family of functions:

\[
g_\lambda(x) = \begin{cases} 
g(x) & \text{if } x \geq 0 \\
\lambda g(x) & \text{if } x < 0. \end{cases}
\]

Then \((g_\lambda)_\lambda\) verifies hypotheses (A) and (B) of Theorem 1.1, provided \(\lambda > 0\). Let us define \(G_\lambda(x) = \int_0^x g_\lambda(\xi) \, d\xi\); let \(\lambda_\ast = G(x_1)/G(x_2) > 0\), then \(G_\lambda_\ast(x_1) = G_\lambda_\ast(x_2)\). Hence also hypotheses (D) and (E) hold and the differential equation:

\[
\dot{x} + f(x)\dot{x} + g_\lambda(x) = 0, \]

has a unique isolated periodic solution.
3.2 Case II: deform $F$

Let us assume $G(x_1) < G(x_2)$. The idea is now to modify the roots of $F$ in such a way hypothesis (D) holds. We do this in a simple way, more sophisticated ones are possible.

Let $\lambda > 0$ and let us introduce the 1–parameter family of functions $(F_\lambda)_\lambda$, defined by:

$$F_\lambda(x) = \begin{cases} F(x) & \text{if } x \geq 0 \\ F(\lambda x) & \text{if } x < 0, \end{cases}$$

clearly $(F_\lambda)_\lambda$ verifies hypothesis (E) if $F$ does; $(F_\lambda)_\lambda$ is no longer Lipschitz at $x = 0$ but existence and uniqueness of the Cauchy problem are still verified.

Thanks to the form of $g$ and hypothesis on $G$, there exists a unique $x_2^* < 0$ such that $G(x_2^*) = G(x_1)$, moreover $x_2 < x_2^*$. Let $\lambda_* = \frac{|x_2|}{|x_2^*|}$ and $\bar{x}_\lambda = x_2/\lambda_*$. We claim that $\bar{x}_\lambda$ is the unique negative zeros of $F_\lambda(x)$. Hence hypotheses (C) and (D) hold, in fact: $F_\lambda$ has three zeros, $x_0, x_1 > 0$ (as $F$ does) and $\bar{x}_\lambda$, moreover $G(\bar{x}_\lambda) = G(x_2^*) = G(x_1)$. Hence

$$\begin{cases} \dot{x} = y - F_\lambda(x) \\ \dot{y} = -g(x), \end{cases}$$

has a unique limit cycle.

3.3 Polynomial Case

Let us consider a polynomial $P_{2n+1}(x) = a_{2n+1}x^{2n+1} + a_{2n}x^{2n} + \cdots + a_1x$, assume $n \geq 1$, $a_{2n+1} > 0$ and hypothesis (C) doesn’t hold. We claim that we can introduce a modified Polynomial $P_\lambda(x) = P_{2n+1}(x) - \lambda x$ and a function $g$ verifying hypotheses (A), (B) and (D) such that

$$\begin{cases} \dot{x} = y - P_\lambda(x) \\ \dot{y} = -g(x), \end{cases}$$

has a unique limit cycle.

$P_{2n+1}(x)$ has at most $2n$ local maxima and minima, so let us define:

$$\begin{align*}
\xi_+ &= \min \{x > 0 : \forall y > x : P'_{2n+1}(y) > 0 \text{ and } P''_{2n+1}(y) > 0\} \\
\xi_- &= \max \{x < 0 : \forall y < x : P'_{2n+1}(y) > 0 \text{ and } P''_{2n+1}(y) > 0\}.
\end{align*}$$
Let us consider $\lambda_\pm \geq 0$ such that:

\[ P_{2n+1}(x) \leq \lambda_+ x \quad \text{for all } 0 < x < \xi_+ \text{ and } P_{2n+1}(x) \geq \lambda_- x \quad \text{for all } \xi_- < x < 0. \]

Such $\lambda_\pm$ can be obtained as follows. Consider straight lines $y = \mu x$ tangent to $y = P_{2n+1}(x)$ for $x \in (0, \xi_+)$, they are in finite number, so one can take $\lambda_+ = \max |\mu_i|$; if $P_{2n+1}(x) < 0$ on $(0, \xi_+)$ we set $\lambda_+ = 0$. A similar construction can be done for $\lambda_-$. 

Let $\lambda = \max\{\lambda_+, \lambda_-\}$ then we claim that for all $\lambda > \lambda$, $\lambda(x) = P_{2n+1}(x) - \lambda x$ satisfies hypothesis (C). By construction $\lambda(x) < 0$ for all $x \in (0, \xi_+)$ and $\lambda(x) > 0$ for all $x \in (\xi_-, 0)$. Because $a_{2n+1} > 0$, for sufficiently large $|x|, \lambda(x)$ has the same sign than $x$, then for $x > 0$ large enough, $\lambda(x) > 0$, hence there is at least one zeros of $\lambda(x)$. Actually this will be the only one. For suppose there are more zeros \(^2\) and call them $x_1 < x_2 < x_3$; by construction for all $x \in (x_1, x_2)$ we have $P_{2n+1}(x) > \lambda x$ whereas $P_{2n+1}(x) < \lambda x$ for $x \in (x_2, x_3)$. This implies $P_{2n+1}(x)$ non–convex for $x > \xi_+$, against the definition of $\xi_+$. The case for negative $x$ can be handle in a similar way. Let us call $x_1$ the positive zeros and $x_2$ the negative one. Summarizing: $\lambda(x)$ has threes real zeros: $x_0 = 0, x_2 < 0 < x_1$, moreover $\lambda(x) < 0$ for $0 < x < x_1$, and $\lambda(x) > 0$ for $x_2 < x < 0$. Remark that $x_1 > \xi_+$ and $x_2 < \xi_-$, namely $\lambda(x)$ is monotone increasing outside $[x_2, x_1]$.

Let $g$ be any locally Lipschitz function such that: $x g(x) > 0$ for $x \neq 0$ and $\int_{x_2}^{x_1} g(\xi) \, d\xi = 0$, then Theorem 1.1 applies and (8) has a unique limit cycle.

### 3.4 Generalization of the polynomial case.

In this section we will generalize the result of the previous section, by proving an existence and uniqueness result for the Liénard equation.

**Theorem 3.1** Let us consider the Liénard equation:

\[
\ddot{x} + f(x)\dot{x} + g(x) = 0, \tag{9}
\]

where $f$ and $g$ verify:

1. \(f\) is continuous and $g$ is locally Lipschitz;
2. \(\lim_{x \to \pm \infty} f(x) = +\infty\) and $xg(x) > 0$ for all $x \neq 0$.

Then there exist $\lambda$, such that for all $\lambda \geq \lambda$ there exists $\mu = \mu(\lambda)$ and system:

\[
\ddot{x} + f_\lambda(x)\dot{x} + g_\mu(x) = 0, \tag{10}
\]

\(^2\) They will be at least three, if transversal, because $\lambda(x_+) < 0$ and $\lambda(x) > 0$ for $x$ large enough. Non–transversal zeros can be removed by small increment of $\lambda$. 

10
has a unique limit cycle, where \( f_\lambda(x) = f(x) - \lambda \) and \( g_\mu \) will be defined in (11).

**Remark 3.2** Hypothesis (B’) is a strong one, even if it is always verified for the important class of polynomial Liénard equations. It can be relaxed by assuming \( \lim_{x \to \pm \infty} F(x) = \pm \infty \) and \( F \) to be monotone increasing outside some interval containing the origin, where as usual \( F(x) = \int_0^x f(\xi) \, d\xi \).

**Proof.** For any \( \lambda_1 > f(0) \), system (9) where \( f_\lambda(x) = f(x) - \lambda_1 \) replaces \( f(x) \), has at least a limit cycle (see Theorem 3 of [10]). Then one can find a \( \lambda \geq \lambda_1 \) such that for all \( \lambda \geq \hat{\lambda} \), \( F_\lambda(x) = -\lambda x + \int_0^x f(\xi) \, d\xi \) verifies hypotheses of Theorem 1.1. Just use monotonicity of \( F \), as we did in the previous section for the polynomial case, to ensure that with \( \lambda \) large enough, \( F_\lambda \) has only two non–zeros roots and it is monotone increasing outside the interval whose boundary is formed by the two non–zeros roots.

Let us call \( x_2(\lambda) < 0 < x_1(\lambda) \), the non–zeros roots of \( F_\lambda(x) = 0 \). Then we can modify \( g \) (for instance as we did in § 3.1) introducing:

\[
g_\mu(x) = \begin{cases} g(x) & \text{if } x \geq 0; \\ \mu g(x) & \text{if } x < 0, \end{cases}
\]  

in such a way \( \int_{x_2}^{x_1} g(\xi) \, d\xi = 0 \). Namely also hypothesis (D) of Theorem 1.1 holds, and so system 10 has a unique limit cycle. \( \square \)

The role of \( f \) and \( g \) in the previous Theorem can be in some sense inverted. More precisely, one can prove the following result

**Remark 3.3** Let us given the global center system:

\[
\ddot{x} + g(x) = 0,
\]  

with \( g \) locally Lipschitz, \( xg(x) > 0 \) for \( x \neq 0 \), \( G(x) = \int_0^x g(\xi) \, d\xi \) and assume \( \lim_{x \to \pm \infty} G(x) = +\infty \). Take any \( x_2 < 0 < x_1 \) such that \( G(x_2) = G(x_1) \) then we can perturb (12) by adding any continuous friction term \( f(x)\dot{x} \), such that \( F(x) = \int_0^x f(\xi) \, d\xi \) verifies \( F(x_1) = F(x_2) = 0 \) and \( F(x) \) is monotone increasing outside the interval \([x_2, x_1]\), obtaining a Liénard system: \( \ddot{x} + f(x)\dot{x} + g(x) = 0 \) with one and only one limit cycle.
