Spin identification of heavy nonstandard bosons in
dilepton and diphoton events at the LHC

P. Osland, A. A. Pankov, N. Paver and A. V. Tsytrinov

Abstract

New Physics scenarios generally predict the existence of very heavy quantum states that
can possibly manifest themselves as peaks in the cross sections at the LHC. For values
of the parameters in certain domains, different nonstandard models can generate peaks
with the same mass and same number of events. In this case, the spin determination of a
peak, requiring the angular analysis of the events, becomes crucial in order to identify the
relevant nonstandard source. We here discuss, using a particularly suitable symmetrically
integrated angular asymmetry applied to Drell-Yan dilepton and diphoton events at LHC,
the identification reach on the exchanges in these reactions of the following heavy bosons:
spin-2 Randall-Sundrum graviton excitations; spin-1 heavy neutral gauge bosons $Z'$; and
spin-0 SUSY $R$-parity violating sneutrinos.
1 Introduction

The occurrence of the heavy bosons predicted by models beyond the standard model (SM), with mass scales $M \gg M_{W,Z}$, can be signalled by the observation of (narrow) peaks in the cross sections for reactions among standard model particles at the high energies available at the LHC. However, the observation of a peak/resonance at some large mass $M = M_R$ may not be sufficient to identify its underlying nonstandard model, in the multitude of potential sources of such a signal. Indeed, in “confusion regions” of the parameters, different models can give the same $M_R$ and same number of events under the peak. In that case, the test of the peak/resonance quantum numbers, in the first place of the spin, is needed to discriminate the models against each other in the confusion regions. Specifically, one defines for the individual nonstandard scenarios a discovery reach as the maximum value of $M_R$ for peak observation over the SM background, and an identification reach as the maximum value of $M_R$ for which the model can be unambiguously discriminated from the other competing ones as the source of the peak.

Particularly clean signals of heavy neutral resonances are expected in the inclusive reactions at the LHC:

$$p + p \rightarrow l^+l^- + X \quad (l = e, \mu) \quad \text{and} \quad p + p \rightarrow \gamma\gamma + X,$$

where they can show up as peaks in the dilepton (and diphoton) invariant mass $M$. While the total resonant cross section determines the number of events, hence the discovery reaches on the considered models, the angular analysis of the events allows to discriminate the spin-hypotheses from each other, due to the (very) different characteristic angular distributions. In the next sections we discuss the identification of the spin-2, spin-1 and spin-0 hypotheses, modelled by the Randall-Sundrum model with one warped extra dimension [1], a set of $Z'$ models [2], and the $R$-parity violating sneutrino exchange [3], respectively.

2 Cross sections and center-edge asymmetry

The total cross section for a heavy resonance discovery in the events (1.1) at an invariant dilepton (or diphoton) mass $M = M_R$ (with $R = G, Z', \tilde{\nu}$ denoting graviton, $Z'$ and sneutrino, respectively) is:

$$\sigma(pp \rightarrow R) \cdot \text{BR}(R \rightarrow l^+l^-) = \int_{-z_{\text{cut}}}^{z_{\text{cut}}} dz \int_{M_R-\Delta M/2}^{M_R+\Delta M/2} dM \int_{y_{\text{min}}}^{y_{\text{max}}} dy \frac{d\sigma}{dM dy dz}. \quad (2.2)$$

Resonance spin-diagnosis makes use of the comparison between the different differential angular distributions [4,5]:

$$\frac{d\sigma}{dz} = \int_{M_R-\Delta M/2}^{M_R+\Delta M/2} dM \int_{y_{\text{min}}}^{y_{\text{max}}} dy \frac{d\sigma}{dM dy dz} dy. \quad (2.3)$$

In Eqs. (2.2) and (2.3), $z = \cos \theta_{cm}$ and $y$ are the lepton-quark (or photon-quark) angle in the dilepton (or diphoton) center-of-mass frame and the dilepton rapidity, respectively, and cuts on phase space due to detector acceptance are indicated. Furthermore, $\Delta M$ is an invariant mass bin around $M_R$, reflecting the detector energy resolution, see for
instance Ref. [6]. To evaluate the number $N_S$ of resonant signal events, time-integrated luminosities of 100 and 10 fb$^{-1}$ will be assumed, as well as 90% reconstruction efficiencies for both electrons and muons and 80% for photons [7]. Typical experimental cuts are: $p_T > 20$ GeV and pseudorapidity $|\eta| < 2.5$ for both leptons; $p_T > 40$ GeV and $|\eta| < 2.4$ for photons. To evaluate Eqs. (2.2) and (2.3), the parton subprocess cross sections will be convoluted with the CTEQ6 parton distributions of Ref. [8]. Next-to-leading QCD effects can be accounted for by $K$-factors, and for simplicity of the presentation we here adopt a flat value $K = 1.3$ for all considered processes.

In practice, due to the completely symmetric $pp$ initial state, the event-by-event determination of the sign of $z$ may at the LHC be not fully unambiguous. This difficulty may be avoided by using as the basic observable for the angular analysis the $z$-evenly integrated center-edge angular asymmetry, defined as [9–12]:

$$A_{CE} = \frac{\sigma_{CE}}{\sigma} \quad \text{with} \quad \sigma_{CE} \equiv \left[ \int_{-z_c}^{z_c} \left( \int_{-z_c}^{z_c} \frac{d\sigma}{dz} \right) - \left( \int_{-z_c}^{z_c} \frac{d\sigma}{dz} \right) \right] d\sigma d\tau. \quad (2.4)$$

In Eq. (2.4), $0 < z^* < z_{cut}$ defines the separation between the “center” and the “edge” angular regions and is a priori arbitrary, but the numerical analysis shows that it can be “optimized” to $z^* \simeq 0.5$. The additional advantage of using $A_{CE}$ is that, as being a ratio of integrated cross sections, it should be much less sensitive to systematic uncertainties than the “absolute” distributions (examples are the $K$-factor uncertainties from different possible sets of parton distributions and from the choice of factorization vs renormalization mass scales).

3 Nonstandard interactions and relevant angular distributions

We list, for the nonstandard models of interest here, the basic features relevant to the angular analysis and the spin-identification.

3.1 RS model with one compactified extra dimension

The simplest version [1], originally proposed as a rationale for the gauge hierarchy problem $M_{EW} \ll M_{Pl}$, consists of one warped extra spatial coordinate $y$ with exponential warp factor $\exp (-k\pi |y|)$ (with $k > 0$ the 5D curvature assumed of order $M_{Pl}$), and two three-dimensional branes placed at a compactification distance $R_c$ in $y$. The SM fields are localized to the so-called TeV brane, while gravity originates on the other one, the so-called Planck brane, but is allowed to propagate in the full 5D space. The consequence of the chosen space-time geometry is that, in the reduction to four dimensions, a Planck-brane mass spectrum with characteristic scale of order $M_{Pl} = 1/\sqrt{8\pi G_N} \simeq 2.4 \times 10^{15}$ GeV, is exponentially “warped” down to the TeV-brane, and the cut-off on the effective theory becomes there $\Lambda_{\pi} = M_{Pl} \exp (-k\pi R_c)$. For $kR_c \simeq 12$, $\Lambda_{\pi}$ is of the TeV order and this opens up the appealing possibility of observing gravitational effects at the LHC energies. Notably, these signatures consist of a tower of spin-2 graviton excitations that can be exchanged in processes (1.1) and show up as narrow peaks in $M$ with the specific mass spectrum $M_n = x_n k \exp (-k\pi R_c)$, of order $\Lambda_{\pi} \sim$ TeV ($x_n$ are the roots of $J_1(x_n) = 0$), and couplings to SM particles of order $1/\Lambda_{\pi}$. 

3
The model can be conveniently parametrized in terms of $M_G$, the mass of the lowest graviton excitation, and of the “universal” dimensionless coupling $c = k/M_{Pl}$. Theoretically, the expected “natural” ranges are $0.01 < c < 0.1$ and $\Lambda_\pi < 10$ TeV [13]. Current 95% CL experimental limits [14] are in the range $M_G > 600$ GeV (for $c \approx 0.01$) up to $M_G > 1.05$ TeV (for $c \approx 0.1$).

For dilepton production, in self-explaining notations and with $\epsilon_q^G$, $\epsilon_q^G$ and $\epsilon_q^{SM}$ the fractions of $G$-events under the $M_R$-peak initiated by $q\bar{q}$, $gg$ and the SM background, respectively, the $z$-even distributions needed in (2.4) can at the leading order be expressed, as [15]:

$$\frac{d\sigma^G}{dz} = \frac{3}{8}(1 + z^2)\sigma_q^{SM} + \frac{5}{8}(1 - 3z^2 + 4z^4)\epsilon_q^G + \frac{5}{8}(1 - z^4)\epsilon_q^G, \quad (3.5)$$

and:

$$A_{CE}^G = \epsilon_q^{SM} A_{CE}^{SM} + \epsilon_q^G \left[ 2z^5 + \frac{5}{2}z^4(1 - z^2) - 1 \right] + \epsilon_q^G \left[ \frac{1}{2}z^5(5 - z^2) - 1 \right]. \quad (3.6)$$

For the diphoton events, the leading order RS resonance exchange contributions to $q\bar{q} \rightarrow G \rightarrow \gamma\gamma$ and $gg \rightarrow G \rightarrow \gamma\gamma$ can analogously be written as [16]:

$$\frac{d\sigma^G}{dz} = \frac{5}{8}(1 - z^4)\epsilon_q^G + \frac{5}{12}(1 + 6z^2 + z^4)\epsilon_q^G, \quad (3.7)$$

and:

$$A_{CE}^G = \epsilon_q^G \left[ \frac{1}{2}z^5(5 - z^2) - 1 \right] + \epsilon_q^G \left[ -1 + \frac{5}{8}z^3 + \frac{5}{4}z^3 + \frac{1}{8}z^5 \right]. \quad (3.8)$$

Next-to-leading order QCD effects, and the corresponding $K$-factors, have been evaluated in Ref. [17] and in Ref. [18] for the dilepton and the diphoton channels, respectively. One important remark is that for the diphoton channel, due to spin-$1\neq \gamma\gamma$, the viable hypotheses reduce to spin-$2$ and spin-$0$ exchanges only and, moreover, the RS model makes the definite prediction $\text{BR}(G \rightarrow \gamma\gamma)/\text{BR}(G \rightarrow l^+l^-) \approx 2$ [15].

### 3.2 Heavy neutral gauge bosons

The spin-1 hypothesis is in process [11] realised by $q\bar{q}$ annihilation into lepton pairs through $Z'$ intermediate states [2]. Such bosons are generally predicted by electroweak models beyond the SM, based on extended gauge symmetries. Generally, $Z'$ models depend on $M_{Z'}$ and on the left- and right-handed couplings to SM fermions. In the sequel, results will be given for a popular class of models for which the values of these couplings are fixed theoretically, so that only $M_{Z'}$ is a free parameter. These are the $Z'_Y$, $Z'_d$, $Z'_q$, $Z'_{LR}$, $Z'_{ALR}$ models, and the “sequential” $Z'_{SSM}$ model with $Z'$ couplings identical to the Z ones. Current experimental lower limits (95% CL) on $M_{Z'}$ depend on models, and range from 878 GeV for $Z'_d$ up to 1.03 TeV for $Z'_{SSM}$ [19].

The $z$-even angular distributions for the partonic subprocesses $q\bar{q} \rightarrow Z' \rightarrow l^+l^-$ have the same form as in the SM and, therefore, the resulting $A_{CE}$ is the same for all $Z'$ models:

$$\frac{d\sigma^{Z'}}{dz} = \frac{3}{8}(1 + z^2)[\sigma_q^{SM} + \sigma_q^{Z'}]; \quad (3.9)$$

$$A_{CE}^{Z'} \equiv A_{CE}^{SM} = \frac{1}{2}z^5(z^2 + 3) - 1. \quad (3.10)$$
Consequently, the $A_{CE}$-based angular analysis should have a considerable degree of $Z'$ model independence. A discussion of next-to-leading QCD corrections can be found, for instance, in Ref. [20].

### 3.3 $R$-parity violating sneutrino exchange

$R$-parity is defined as $R_p = (-1)^{(2S+3B+L)}$, and distinguishes particles from their superpartners. In scenarios where this symmetry can be violated, supersymmetric particles can be singly produced from ordinary matter. In the dilepton process of interest here, a spin-0 sneutrino can be exchanged through the subprocess $d\bar{d} \rightarrow \tilde{\nu} \rightarrow l^+l^-$ and manifest itself as a peak at $M = M_{\tilde{\nu}}$ with a flat angular distribution [3]:

$$\frac{d\sigma^{\tilde{\nu}}}{dz} = \frac{3}{8}(1 + z^2)\sigma_{SM}^q + \frac{1}{2}\sigma_{q}^{\tilde{\nu}},$$

$$A_{CE}^{\tilde{\nu}} = \epsilon_{SM}^{q} A_{SM}^{q} + \epsilon_{q}^{\tilde{\nu}}(2z^* - 1).$$

(3.11)

(3.12)

Results on higher QCD orders and supersymmetric QCD corrections available in the literature indicate the possibility of somewhat large $K$-factors [21,22]. The cross section is proportional to the $R$-parity violating product $X = (\lambda')^2 B_l$ where $B_l$ is the sneutrino leptonic branching ratio and $\lambda'$ the relevant sneutrino coupling to the $d\bar{d}$ quarks. Current limits on the relevant $\lambda'$s are of the order of $10^{-2}$ [23], and the experimental 95% CL lower limits on $M_{\tilde{\nu}}$ range from 397 GeV (for $X = 10^{-4}$) to 866 GeV (for $X = 10^{-2}$) [19]. We may take for $X$, presently not really constrained for sneutrino masses of order 1 TeV or higher, the (rather generous) interval $10^{-5} < X < 10^{-1}$.

### 4 Spin-diagnosis using $A_{CE}$

The nonstandard models briefly described in the previous section can mimic each other as sources of an observed peak in $M$, for values of the parameters included in so-called “confusion regions” (of course included in their respective experimental and/or theoretical discovery domains), where they can give the same number of signal events $N_S$. The $M_R$-$N_S$ plots in Fig. 1 show as examples the graviton vs sneutrino and graviton vs $Z'$ confusion domains as well as the number of events needed for 5-σ discovery at the 14 TeV LHC with luminosity $L_{int} = 100$ fb$^{-1}$.

In such confusion regions, one can try to discriminate models from one another by means of the angular distributions of the events, directly reflecting the different spins of the exchanged particles. We continue with the examples of confusion regions in Fig. 1 and start from the assumption that an observed peak at $M = M_R$ is the lightest spin-2 graviton (thus, $M_R = M_G$). We define a “distance” among models accordingly:

$$\Delta A_{CE}^{Z'} = A_{CE}^{G} - A_{CE}^{Z'}$$

$$\Delta A_{CE}^{\tilde{\nu}} = A_{CE}^{G} - A_{CE}^{\tilde{\nu}}.$$ (4.13)

To assess the domain in the $(M_G, c)$ plane where the competitor spin-1 and spin-0 models giving the same $N_S$ under the peak can be excluded by the starting RS graviton hypothesis, a simple-minded $\chi^2$-like criterion can be applied, which compares the deviations (4.13) with the statistical uncertainty $\delta A_{CE}^{G}$ pertinent to the RS model (systematic uncertainties can easily be included). We impose the two conditions

$$\chi^2 \equiv \left| \frac{\Delta A_{CE}^{Z'} / \delta A_{CE}^{G}}{\Delta A_{CE}^{\tilde{\nu}} / \delta A_{CE}^{G}} \right|^2 > \chi^2_{CL}.$$ (4.14)
Here, $\chi^2_{\text{CL}}$ specifies a desired exclusion confidence level (3.84 for 95% CL). This condition determines the minimum number of events, $N^\text{min}_S$, needed to exclude the spin-1 and spin-0 hypotheses (hence to establish the graviton spin-2), and this in turn will determine the RS graviton identification domain in the $(M_G, c)$ plane. Of course, an analogous procedure can be applied to the identification of $Z'$ and $\tilde{\nu}$ exchanges against the two competing ones. In the next section we review the results obtained for the three spin-identification analyses based on $A_{\text{CE}}$. Recents attempts based on, alternatively, $y$-integrated asymmetries have been proposed in Ref. [24].

Figure 2 shows, for LHC energy and luminosity the same as for Fig. 1, the deviations (4.13) vs $z^*$ for $M_G = 1.6$ TeV and $c = 0.01$, assuming the same $M_R$ and number of peak events for the spin-1 $Z'$ and the spin-0 $\tilde{\nu}$ hypotheses. The error bars are the statistical 2-σ uncertainties on $A^G_{\text{CE}}$. Figure 2 shows, as anticipated, that $z^* \simeq 0.5$ is “optimal”, in the sense that at this value there is maximal sensitivity to the deviations among models.
and, moreover, the $\chi^2$ is found to be rather smooth. By imposing the conditions (4.14), one finds the minimum number of events $N_S^{\text{min}}$ vs $M_G$ (and with $0.01 < c < 0.1$), needed to exclude at 95% CL the spin-1 as well as the spin-0 hypotheses once the spin-2 one has been assumed to be "true". Such $N_S^{\text{min}}$ are reported in Fig. 2, right panel. Notice from this figure that the "theoretically favored" region is severely restricted to the domain within the $\Lambda_{\pi} = 10$ TeV and the $c = 0.1$ contours (green).

Figure 3: RS graviton discovery and identification from dilepton events.

Figure 4: RS graviton discovery and identification from diphoton events.

Figure 3 shows the expected lowest lying graviton identification domain at 95% CL in the $(M_G, c)$ plane from dilepton events ($l = e, \mu$ combined) at 14 TeV with time-integrated luminosities of 10 and 100 fb$^{-1}$ [10]. Basically, in this figure, the domain to the left of the line "G" is the discovery domain; that to the left of the "V" line is the exclusion domain of the $Z'$ hypothesis; and that to the left of the "S" line represents the domain where the $\tilde{\nu}$ hypothesis (as well as the $Z'$) can be excluded, hence the spin-2 identified. From the two panels of Fig. 3 one can read the expected graviton identification limits: $M_G < 1.1$ or 2.4 TeV for $c = 0.01$ or 0.1, respectively, at 10 fb$^{-1}$; $M_G < 1.6$ or 3.2 TeV for $c = 0.01$ or 0.1, respectively, at 100 fb$^{-1}$. The identification reach could therefore be a significant portion of the discovery domain, especially for the higher luminosity. On the other hand, the discovery domain is really constrained by the condition $\Lambda_{\pi} < 10$ TeV, if applied literally.
Figure 4 shows a preliminary attempt to assess the 95% CL identification reach on
the RS spin-2 graviton excitation from the diphoton events in (1.1), by means of the $A_{CE}$
analysis, for $L_{int} = 100 ~ fb^{-1}$ and cuts and photon reconstruction efficiencies as outlined
in the Introduction. In this case, only a hypothetical spin-0 resonance decaying to two
photons must be excluded. The curves in those plots must be interpreted analogously to
those in Fig. 3. Specifically, the left panel shows the $N_{S}^{\text{min}}$ vs $M_{G}$ for RS identification
(or scalar hypothesis rejection) within $0.01 < c < 0.1$, while the right panel shows the
identification domain in the $(M_{G}, c)$ plane. This tentative example shows that diphoton
events might have an identification sensitivity to the RS graviton comparable to the
dilepton ones, with the spin-1 automatically excluded.

4.2 Spin-1 $Z'$ identification

Due to our choice of a family of models where the values of the $Z'$ coupling constants to
quarks and leptons have theoretically pre-determined values, in the $(M_{R} - N_{S})$ plot in
Fig. 1 these scenarios are simply represented by lines, with now $M_{R} = M_{Z'}$. The figure
shows that, at the LHC luminosity assumed there, some models, namely, the $Z'_{ALR}$ and
the $Z'_{SSM}$ can be discriminated from the RS spin-2 resonance (but not from the spin-0 $\tilde{\nu}$)
already at the level of event rates. The other $Z'$s share confusion regions with both spin-2
and spin-0 hypotheses.

The $A_{CE}$-based angular analysis can be applied quite similar to the preceding case,
this time assuming that an observed peak in $M$ is due to a $Z'$, and evaluating the minimal
number of events needed for excluding the spin-2 and spin-0 hypotheses. At the 100 fb$^{-1}$
luminosity assumed in Fig. 1, $N_{S}^{\text{min}}$ turns out to be about 130 and 200 for exclusion of
spin-2 and spin-0, respectively. This information can easily be turned into identification
limits in terms of the relevant $M_{Z'}$. For the 14 TeV LHC nominal energy and luminosity
100 fb$^{-1}$, one could establish the $Z'$ hypothesis (by exclusion of spin-2 and spin-0) for
$M_{Z'} \leq 3.0 - 3.8$ TeV, depending on the particular model. In addition one can make
pairwise comparisons (hence obtain identification) between the considered $Z'$ models with
same $Z'$ mass on the basis of the different expected statistics, in the 1–2 TeV range for
$M_{Z'}$. Details are discussed in Ref. 11.

4.3 Spin-0 sneutrino identification

Figure 1 shows that the domain in the $R$-breaking parameter $X$ allowed to sneutrinos is
so large that its discovery domain fully includes those of the RS resonance (with $0.01 < c < 0.1$) and of all $Z'$s. The situation would be exactly the same even if we restricted $X$
to the narrower interval $10^{-4}$–$10^{-2}$.

Figure 5 shows, as an example, the sneutrino confusion regions with RS and $Z'$s vs $M_{\tilde{\nu}}$
for 10 fb$^{-1}$, with LHC energy 14 TeV (left panel) and 7 TeV (right panel), respectively.
The $Z'$ models are not all explicitly represented, the relevant curves lie in the domain
between the rightmost ($Z'_{ARL}$) and the leftmost $Z'_{\psi}$ dashed ones. The condition $\Lambda_{\pi} < 10$
TeV is not reported here. One can easily read off the minimal number of events vs $M_{\tilde{\nu}}$
needed for 95% CL exclusion of the RS resonance, of the spin-1 $Z'$ hypotheses, and
both, once a peak in dilepton events has been attributed to sneutrino exchange in (1.1).
One finds that $N_{S}^{\text{min}} \simeq 150$ events are needed for sneutrino identification via $A_{CE}$, the
relevant values of $M_{\tilde{\nu}}$ being constrained to the ranges 1.9–2.7 TeV and 1.1–1.7 TeV for
LHC energies 14 TeV and 7 TeV, respectively. At 14 TeV and the highest luminosity $\mathcal{L}_{\text{int}} = 100 \text{ fb}^{-1}$, the range in $M_{\tilde{\nu}}$ would be 3.0–3.8 TeV. A larger number of events would be necessary if the condition $\Lambda_\pi < 10 \text{ TeV}$ on the RS model were applied literally. A more detailed numerical analysis is reported in Ref. [12].
