Objective
Revascularization is critical for successful ovarian tissue transplantation. Vascular endothelial growth factor (VEGF) and angiopoietin-2 (angpt-2) are the principal mediators of neovascularization. This study was designed to assess VEGF and angpt-2 levels in cryopreserved ovarian tissue after heterotopic autotransplantation.

Methods
Ovarian tissues harvested from ICR mice at 5 to 6 weeks of age were stratified as follows: no cryopreservation (controls, group I); vitrification in VFS-40 (vitrification, group II); and gradual freezing in dimethyl sulfoxide (slow-freezing, group III). Frozen specimens were thawed at room temperature, assaying VEGF and angpt-2 levels 1 week after cryopreservation and 2 weeks after autotransplantation.

Results
VEGF and angpt-2 protein levels were significantly lower in cryopreserved ovaries of groups II and III than in controls (group I, P<0.05), whereas groups II and III did not differ significantly in this regard. After autotransplantation of cryopreserved ovarian tissue, VEGF and angpt-2 protein levels did not differ significantly by technique but tended to be lower than corresponding levels in controls.

Conclusion
Expression of angiogenic factors in ovarian tissue is thought to vary by method of cryopreservation. Our findings indicate that levels of angiogenic factors expressed in cryopreserved ovarian tissue after autotransplantation do not differ appreciably from control levels, regardless of cryopreservation technique.

Keywords: Angiopoietin-2; Cryopreservation; Ovary; Transplantation; Vascular endothelial growth factor
A number of angiogenic factors have been identified as principal mediators of neovascularization. Vascular endothelial growth factor (VEGF) is an endothelial cell mitogen that regulates angiogenesis and blood vessel permeability in transplanted ovarian tissue [8-11]. In addition, angiopoietins are required to regulate vascular ingrowth and stability [11,12]. Angiopoietin-2 (angpt-2) enables endothelial cell migration and proliferation, further promoting angiogenesis in the presence of VEGF. In the absence of VEGF, angpt-2 blocks recruitment of periendothelial support cells, resulting in vascular destabilization and regression [13-15]. This study was aimed at investigating the effects of cryopreservation techniques (vitrification and slow-freezing) on ovarian expression of angiogenic factors by determining the levels of VEGF and angpt-2 in successful heterotopic ovarian autotransplants of mice.

Materials and methods

1. Animals
Female ICR mice were purchased from Koatech (Pyeongtaek, Korea). The mice were housed under light-controlled and temperature-controlled conditions (12 hours of light and 12 hours of darkness, 22±2°C), and were provided with sterile food and water. Mice were treated in accordance with the standard guidelines for laboratory animal care at animal facility of the Gyeongsang National University (GLA-090107-M0001).

2. Ovarian tissue collection
ICR mice (n=30) 5 to 6 weeks of age in three groups (10 each) were anesthetized, and bilateral oophorectomies were performed. Operative wounds were sutured using PolySorb 3-0 layer by layer. Harvested ovaries of the two test groups were subjected to cryopreservation, reserving one ovary of each pair for later autotransplantation (Fig. 1).

The specimens were stratified as follows: no cryopreservation (controls, group I); vitrification in VFS-40 (vitrification, group II); and gradual freezing in dimethyl sulfoxide (slow-freezing, group III).

Experimentation was conducted in two phases. First, angiogenic factors were evaluated in test ovaries (cryopreserved for one week) and in controls. Second, angiogenic factors were evaluated two weeks after autotransplantation of test ovaries. In the control group, non-cryopreserved ovaries were autotransplanted immediately following oophorectomies.

3. Cryopreservation
1) Vitrification
Paired ovaries were immersed 10 minutes in an equilibration solution (EG-20), consisting of 20% ethylene glycol in Dulbecco’s phosphate-buffered saline (m-DPBS) with 10% fetal bovine serum (FBS). This was followed by a 2-minutes immersion in vitrification solution (EFS-40), consisting of 40% ethylene glycol (v/v), 18% Ficoll (w/v), 0.5 mol/L sucrose, and 20% FBS in m-DPBS. The specimens were then loaded onto an electron microscope grid and immediately quick-frozen in liquid nitrogen. After 1 week, a three-step cryoprotectant dilution method was implemented for thawing [16]. One ovary was used for Western blot analysis, the other ovary was reserved for autotransplantation.

2) Slow-freezing
Paired ovaries were transferred to cryovials containing a cryoprotective mixture (Leibovitz L-15 medium, 10% FBS, and 1.5 M dimethyl sulfoxide) for controlled freezing via planar cryochamber. Cooling began at 4°C, proceeding at 2°C/min (past induction of ice nucleation at -7°C) until reaching -35°C. Freezing was accelerated to 25°C/min, plunging the cryovials into liquid nitrogen once a threshold temperature (-140°C) was reached. After 1 week, thawing was carried out at room temperature.

4. Heterotopic autotransplantation and retrieval of ovarian tissue
One ovary of each harvested pair served as heterotopic autotransplant, to be done one week after cryopreservation. Following inhalation anesthesia, the animal’s abdominal wall was
carefully opened, creating space for a graft without breach of peritoneum. Ovaries were affixed to exposed peritoneum using Polysorb 3-0 suture. Two weeks later, the mice were sacrificed and the ovaries were recovered (Fig. 2). Follicles were observed under microscopy, and Western blot analysis was performed.

5. Western blot analysis
Harvested ovaries were preserved in Pro-prep (iNtRON Biotechnology, Seoul, Korea) solution until analysis. Proteins were separated by sodium dodecyl sulfate polyacrylamide gel electrophoresis in 8% gels and blotted onto polyvinylidene fluoride membranes. The blots were blocked (1 hour) using 5% skim-milk in TBST (20 mM Tris-buffered saline and 0.05% Tween 20, pH 7.5) at room temperature for overnight incubation (4°C) with anti-VEGF antibody (1:500). Blots were washed for secondary antibody incubation, followed by washing and detection of immunoreactivity with enhanced chemiluminescence (Amer-sham ECL Reagent, GE Healthcare Biosciences, Pittsburgh, PA, USA). Data were independently generated in triplicate.

6. Statistical analysis
All data were expressed as mean±standard error. Statistical computations relied on standard software (PASW ver. 18.0, SPSS Inc., Chicago, IL, USA). Non-parametric Kruskal-Wallis method was applied for comparisons, using Tukey’s test for post-hoc analysis. Significance was set at P<0.05.

Results
1. Feasibility of cryopreserved ovarian heterotopic autotransplantation
Two weeks after autotransplantation, any viable ovarian tissue found under abdominal wall with observable follicles by microscopy was defined as a successful transplant (Fig. 2). The number of successfully transplanted ovaries was 8/10 in controls (group I), 6/10 with vitrification (group II) and 7/10 with slow-freezing (group III).

![Fig. 2. Autotransplanted mouse ovary: (A) beneath the abdominal wall (arrow), to be assayed after 2 weeks, and (B) on dish with media.](image)

![Fig. 3. Western blot analysis: quantitative analysis by group of (A) vascular endothelial growth factor (VEGF) and (B) angiopoietin-2 (angpt-2) after 1 week of vitrification or slow freezing (no cryopreservation of controls). β-actin was used as internal standard. Data were expressed as mean±standard error of three independent experiments. *P<0.05 vs. cryopreservation groups (vitrification and slow freezing).](image)
2. Impaired angiogenic factor expression after cryopreservation
With cryopreservation, lower levels of VEGF and angpt-2 were expressed relative to controls ($P < 0.05$), and levels did not differ significantly by cryopreservation method (Fig. 3).

3. Expression of angiogenic factors after heterotopic autotransplantation
Two weeks after autotransplantation, whole ovaries removed from mice were analyzed. VEGF and angpt-2 expression in cryopreservation groups trended lower than in controls, but the differences were not significant; and levels did not differ significantly by cryopreservation method (Fig. 4).

Discussion
Banking of ovarian tissue is a promising technique for preservation of fecundity in young female cancer patients [17,18]. Although this strategy is still considered experimental, proof-of-principle has existed for some time. Earlier studies indicate that variable but large fractions of follicles are lost by ischemia while grafts revascularize during their first 2 to 5 days, whereas the impact of cryoinjury is comparatively minor [19,20]. Angiogenesis in frozen-thawed ovarian tissue of rats begins within 48 hours of transplantation, commensurate with increased angpt-2 and VEGF189 mRNA levels, but requires more than 7 days to reach completion [21]. By facilitating angiogenesis and thus limiting the duration of ischemia, reductions in necrotic tissue and fractions of wasted follicles should result, thereby prolonging graft function and potentiating fertility [22].

VEGF was initially credited with the ability to induce vascular leakage/permeability and to promote ingrowth of vessels [23]. Indeed, incubation of human ovarian tissue with VEGF has been shown to improve graft survival [24]. In addition, angpt-2 is required for regulating angiogenesis and for stability of blood vessels [12], as well as securing folliculogenesis during the pre-ovulatory period [15]. Hence, VEGF and angpt-2 levels are important indices of successful cryopreserved ovarian transplants.

Our previous data and present findings have shown that VEGF and angpt-2 are diminished by cryopreservation, regardless of the method utilized. Although vitrification with EFS-40 proved more efficient than slow freezing for preserving angiogenic factors [16] in our earlier work, no differences between vitrification with EFS-40 and slow freezing were evident in the present investigation. Currently, we are unable to explain this discrepancy, other than to implicate a delay in conducting the Western blot analysis after autotransplantation of cryopreserved ovaries in this study.

Slow freezing of ovarian tissue preserves cell morphology and hormone production in the course of freeze-thaw maneuvers [25]. Vitrification also preserves follicular morphology/ viability and stromal density [26]. On the other hand, observed disparities in angiogenic factors with cryopreservation (vs. controls) were largely reversed after autotransplantation. Revascularization of the grafts rapidly up-regulated gene expression of angiogenic factors [27]. In this instance, observed increases in angiogenic factors of test specimens approached levels found in non-cryopreserved controls.

Although the cryopreserved ovarian autotransplants herein are considered successful, tissue necrosis was ample, and reduction in normal tissue was substantial. Apparently, VEGF...
and angpt-2 disruption by cryopreservation does adversely impact angiogenesis and implantation in this setting. Although we have optimized freeze/thaw and autotransplantation procedures for use in several experiments [6,16,28,29], not all ovaries so-treated regained their function, and a certain portion became atretic [30]. This suggests that additional improvements in methodology are in order to enhance ovarian tissue survival.

Because similar levels of angiogenic factors were maintained after autotransplantation with or without prior cryopreservation, we suspect that angiogenesis (as mediated by VEGF and angpt-2) in transplanted states commonly proceeds this way. Likewise, the technique used for cryopreservation, whether vitrification or slow freezing, did not influence expression of angiogenic factors in heterotopic autotransplants. Hence, vitrification is validated as a useful method of ovarian tissue cryopreservation for autotransplantation.

In conclusion, autotransplantation of whole, cryopreserved ovaries beneath the abdominal walls of mice is feasible. Any loss of angiogenic factor expression due to cryopreservation is not method-dependent and is recovered after autotransplantation, similar to non-cryopreserved counterparts. Additional studies are needed to further characterize the roles of angiogenic factors under these circumstances.
