Abstract

Although interferon (IFN) has been often used as immunotherapy for bladder cancer, its efficacy is rather unsatisfactory, demanding further improvement. Combination therapy is one of viable options, and grape seed proanthocyanidin (GSP) could be such an agent to be used with IFN because it has been shown to have anticancer activity. We thus investigated whether combination of IFN and GSP might enhance the overall antiproliferative effect on bladder cancer cells in vitro. Human bladder cancer T24 cells were employed and treated with the varying concentrations of recombinant IFN-α2b (0-100,000 IU/ml), GSP (0-100 μg/ml), or their combinations. IFN-α2b alone led to a ~50% growth reduction at 20,000 (20K) IU/ml, which further declined to ~67% at ≥50K IU/ml. Similarly, GSP alone induced a ~35% and ~100% growth reduction at 25 and ≥50 μg/ml, respectively. When IFN-α2b and GSP were then combined, combination of 50K IU/ml IFN-α2b and 25 μg/ml GSP resulted in a drastic >95% growth reduction. Cell cycle analysis indicated that such an enhanced growth inhibition was accompanied by a G1 cell cycle arrest. This was further confirmed by Western blot analysis revealing that expressions of G1-specific cell cycle regulators (CDK2, CDK4, cyclin E and p27/Kip1) were distinctly modulated with such IFN-α2b/GSP treatment. Therefore, these findings support the notion that combination of IFN-α2b and GSP is capable of additively enhancing antiproliferative effect on T24 cells with a G1 cell cycle arrest, implying an adjuvant therapeutic modality for superficial bladder cancer.

Key words: interferon, proanthocyanidin, combination therapy, bladder cancer.

Introduction

Bladder cancer is the second most common urologic malignancy next to prostate cancer in the United States, and the majority of bladder cancers present as superficial (80%) with 15% presenting as invasive cancer and 5% as metastatic disease (1). Currently, transitional cell carcinoma (TCC) is the most prevalent primary bladder tumor: 50,000 new cases are diagnosed annually and over 10,000 people die of this disease each year (2). Although endoscopic transurethral resection (TUR) is often performed as a primary therapy, 50%-75% of patients will yet recur in 5 years and about 10% progress to invasive disease (2).

Chemotherapy is another viable option but intravesical administration of bacillus Calmette-Guerin (BCG), an attenuated strain of Mycobacterium bovis, is currently the most effective immunotherapy for high-grade and recurrent superficial bladder cancer and carcinoma in situ (CIS) (3). In randomized studies, BCG has been shown to be superior to both mitomy-
cin C and adriamycin (4). Intravesical BCG following TUR has also been associated with a significant improvement in progression and survival compared to TUR alone (5). In fact, this protocol has become established therapy for superficial bladder cancers, resulting in a ~40% reduction in cancer recurrence (6). However, side effects of BCG therapy are common and limit its use in clinical practice, demanding a safer, more effective therapeutic modality with fewer side effects.

Interferons (IFNs) have been often used as immunotherapy for a variety of urologic malignancies including prostate, bladder, and renal cell carcinomas (7-9). Especially, IFN-α is used as an intravesical agent for treating superficial bladder cancer because it may cause only minor local and systemic toxicity (compared to BCG) (10). However, since its response rate in patients has been shown to be lower than that of BCG therapy (10), the efficacy of IFN-α combined with BCG was assessed in pilot clinical trials and animal studies (11,12), indicating the better, improved outcomes. Thus, these studies would certainly encourage further exploration into other alternative combination therapies, which may lead to the safer, more effective and satisfactory results.

Proanthocyanidins are naturally occurring plant polyphenolic bioflavonoids in fruits, vegetables, nuts, seeds, flowers and bark (13). They are known as natural antioxidants, having biological, pharmacological and chemoprotective properties against oxidative stress or harmful free radicals (13-15). For example, hydrogen peroxide-induced oxidative stress was significantly reduced by proanthocyanidins in cultured macrophage and neuroactive PC-12 cells (14). They have exhibited antibacterial, antiviral, anti-inflammatory, and vasodilatory actions as well (13). Particularly, a unique grape seed proanthocyanidin (GSP) has been extensively characterized: it is a standardized water-ethanol extract from red grape seeds, consisting of oligomeric proanthocyanidins as active components (15). GSP has also demonstrated its anticancer (cytotoxic) effect on several malignancies including breast, lung and gastric cancers in vitro (16).

Accordingly, we investigated whether IFN-α, GSP or their combination might demonstrate the antiproliferative effect on bladder cancer cells in vitro. We also explored the underlying mechanism – how the cancer cell growth might be inhibited with such agents, focusing on the cell cycle regulation. More detailed studies are described and discussed herein.

Materials and Methods

Cell culture

The human bladder cancer T24 cells, derived from a patient with TCC, were obtained from the American Type Culture Collection (Manassas, VA). Cells were cultured in McCoy’s 5a medium containing 10% fetal bovine serum, penicillin (100 U/ml), and streptomycin (100 μg/ml), and were maintained at 37 °C in a humidified incubator in an atmosphere of 95% air and 5% CO2. For experiments, cells were seeded in 6-well plates (2 ml per well) or T-75 flasks (10 ml per flask) at the initial cell density of 2 x 10^5 cells/ml and were cultured with recombinant interferon-α2b (IFN-α2b; Schering Corp., Kenilworth, NJ), grape seed proanthocyanidin (GSP; Dry Creek Nutrition, Inc., Modesto, CA) or their combinations. Cell number/viability was then assessed at specified times using the trypan blue exclusion method.

Cell cycle analysis

A FACSscan flow cytometer (Becton-Dickinson, San Jose, CA), equipped with a double discrimination module, was employed for cell cycle analysis. Control or agents-treated cells (~1 x 10^6 cells per condition) were first resuspended in 500 μl of propidium iodide solution (20 μg/ml propidium iodide, 0.2 mg/ml RNase, 0.2 mg/ml EDTA, 0.5% Nonidet P-40) and incubated for 1 h at room temperature in the dark. Following incubation, ~10,000 nuclei from each sample were analyzed on a flow cytometer, and CellFit software was used to quantify cell cycle compartments to estimate the % of cells distributed in the different cell cycle phases.

Western blot analysis

The procedure essentially followed the protocol described previously (17). Briefly, an equal amount of proteins (7 μg) from control and agent-treated cell lysates was resolved by 10% SDS-polyacrylamide gel electrophoresis and transferred to a nitrocellulose membrane. The blot was first incubated for 90 min with the primary antibodies against CDK2, CDK4, cyclin D1, cyclin E, or p27/Kip1 (Santa Cruz Biotechnology, Santa Cruz, CA), followed by incubation with the secondary antibody conjugated with peroxidase for 30 min. The immunoreactive protein bands were detected by chemiluminescence following the manufacturer’s protocol (Kirkegaard and Perry Laboratories, Gaithersburg, MD) and quantified using a scan densitometer (Silk Scientific, Oregon, UT).

Statistical analysis

All data were presented as the mean ± SD (standard deviation), and statistical differences between groups were assessed with either the unpaired Student’s t test or one-way analysis of variance (ANOVA). Values of p<0.05 were considered to indi-
cate statistical significance.

Results

Effects of interferon-α2b and proanthocyanidin on T24 cell growth

To examine possible effects of interferon-α2b (IFN-α2b) and grape seed proanthocyanidin (GSP) on T24 cell growth, cells were cultured with the varying concentrations of IFN-α2b (0-100,000 = 100K IU/ml) or GSP (0-100 μg/ml) for 72 h. IFN-α2b caused a significant (~50%) growth reduction at 20K IU/ml, which further declined to >67% at ≥50K IU/ml (Fig. 1A). Similarly, a ~35% and >90% growth inhibition were attained with 25 and ≥50 μg/ml of GSP, respectively (Fig. 1B). A drastic growth reduction (~90%) with 50 μg/ml GSP was actually due to a cytotoxic effect, evidenced by ~30% of cells having been dead. These results thus show that IFN-α2b and GSP are capable of inhibiting T24 cell growth but GSP can also induce cytotoxic cell death at the higher (≥50 μg/ml) concentrations.

Additive antiproliferative effects of IFN-α2b and GSP

It was tempting to examine whether combinations of IFN-α2b and GSP might improve the antiproliferative effects. As 25 μg/ml of GSP appeared to induce a moderate (~35%) growth inhibition (Fig. 1B), this concentration was used in combination with the varying concentrations of IFN-α2b. Such studies showed that combinations of GSP (25 μg/ml) and IFN-α2b at 10K IU/ml (little effect by itself), 20K IU/ml (a ~50% inhibitory effect), and 50K IU/ml (a ~67% inhibitory effect) led to the improved 43%, 79%, and >95% growth reduction (p<0.05), respectively (Fig. 2). Thus, the IFN-α2b/GSP combinations appear to induce the additive antiproliferative effects on T24 cells.

Fig. 2. Effects of combination of IFN-α2b and GSP on cell growth. Cells were treated with combinations of GSP (25 μg/ml) and 10K, 20K, or 50K IU/ml of IFN-α2b for 72 h, and cell growth was assessed by the % of viable cell numbers relative to that in control (100%). The data are mean ± SD from three separate experiments (*p<0.05; **p<0.03).

Effects of IFN-α2b and GSP on cell cycle

To explore the mechanism of such additive effects of the IFN-α2b/GSP combinations, cell cycle analysis was performed using the specific concentrations of IFN-α2b (20K IU/ml) and GSP (25 μg/ml), which seemed to be rather suitable for this study. After T24 cells were treated with IFN-α2b (20K IU/ml), GSP (25
μg/ml), or their combination for 72 h, the results of cell cycle analysis were then summarized in Table 1. Compare to cell numbers of the G₁ and S phases in controls, significant changes in those numbers (p<0.05) were seen with IFN-α₂b treatment, while GSP alone showed only the marginal effects. In contrast, the IFN-α₂b/GSP combination induced a 58% increase and 64% decrease in G₁ and S phase cell numbers (p<0.05), respectively. This cell accumulation in the G₁ phase is known as a G₁ cell cycle arrest (18). Thus, the IFN-α₂b/GSP combination may primarily target the G₁-S phase transition in the cell cycle, subsequently leading to the growth cessation.

**Table 1 Effects of IFN-α₂b and GSP on Cell Cycle Phase Distributions.**

| Conditions                  | % of Cells in Cell Cycle Phases |
|-----------------------------|---------------------------------|
|                             | G₁     | S       | G₂/M  |
| Control                     | 49.3 ± 4.7 | 38.1 ± 2.8 | 12.6 ± 1.4 |
| + IFN-α₂b (20K IU/ml)       | 61.7 ± 4.6* | 26.7 ± 3.1* | 11.6 ± 1.1 |
| + GSP (25 μg/ml)            | 56.7 ± 5.0 | 33.2 ± 2.9 | 10.1 ± 1.6 |
| + IFN-α₂b (20K)/GSP (25)   | 77.9 ± 4.3* | 13.6 ± 1.4* | 8.5 ± 0.9 |

All data are mean ± SD from three separate experiments.

* p<0.05 (compared to those in Control).

**Down-regulation of G₁ cell cycle regulators by IFN-α₂b/GSP combination**

To confirm such an IFN-α₂b/GSP-induced G₁ cell cycle arrest, we also examined its effects on the specific cell cycle regulators for the G₁-S phase transition (18). After cells were treated with or without the IFN-α₂b (20K IU/ml)/GSP (25 μg/ml) combination for 72 h, the expressions of CDK2, CDK4, cyclin D₁, cyclin E, and p27/Kip1 were analyzed on Western blots. Such analysis revealed that the expressions of CDK2, CDK4 and cyclin E were drastically reduced by ~80% with the IFN-α₂b/GSP treatment (compared to those in controls), although no change in cyclin D₁ was observed (Fig. 3). In contrast, p27/Kip1 protein, a CDK2 inhibitor, was significantly (~2.7 fold) up-regulated in IFN-α₂b/GSP-treated cells (Fig. 3). Thus, altered expressions of these regulators would provide the further evidence for a blockage of G₁-S phase transition, confirming that the IFN-α₂b/GSP-induced growth inhibition is indeed mediated through a G₁ cell cycle arrest.

**Effects of IFN-α₂b/GSP combination on proliferation of other cancer cells**

Now, one may raise the question if the IFN-α₂b/GSP combination would also demonstrate its enhanced antiproliferative effect on other bladder cancer cells or different cancer cell types. This was tested using another bladder cancer 5637 cells, prostate cancer PC-3 cells, and renal cancer ACHN cells, which had been treated with IFN-α₂b (20K IU/ml), GSP (25 μg/ml), or their combination for 72 h. Figure 4 shows the effects of these agents on proliferation of three cancer cell lines. Overall, all cancer cells treated with various agents exhibited altered growth patterns, which were significantly different from their respective control cells (p<0.05). IFN-α₂b alone was capable of inducing a ~50% growth inhibition in both PC-3 and ACHN cells but a ~30% inhibition in 5637 cells. GSP alone caused a lesser but 22-37% growth reduction in all these cells. Nevertheless, the IFN-α₂b/GSP combination resulted in an enhanced 70%, 71%, and 68% growth inhibition in 5637, PC-3, and ACHN cells, respectively. Thus, these results suggest that the IFN-α₂b/GSP combination may commonly demonstrate its potentiated antiproliferative-
tive effect on not only T24 cells but also a variety of human cancer cells.

yet required for establishing the more potent, safer, and cost-effective treatment modalities.

Fig. 4. Growth inhibitory effect of IFN-α2b/GSP combination on various cancer cells. Bladder cancer 5637, prostate cancer PC-3, and renal cancer ACHN cells were treated with IFN-α2b (20K IU/ml), GSP (25 μg/ml), or their combination for 72 h, and cell growth was assessed by the % of viable cell number (in each condition) relative to that in respective control cells. The growth profile of T24 cells is also shown for comparison. All data are mean ± SD from three separate experiments, showing statistically significant differences (p<0.05) compared to respective controls (100%).

Discussion

Although IFN-α has been often used as immuno-

therapy for bladder cancer because of its relatively low toxicity (compared to BCG), its less efficacy has been also inquired for a significant improvement. Additionally, IFN-α therapy has several drawbacks, such as high cost and repeated administration. A standard intravesical IFN-α instillation is often carried out with 50-100 million IU of IFN-α (19), but whether this high dosage would be sufficient to induce optimal immunity is uncertain because of its short retention time inside the bladder (19). Accordingly, to improve the efficacy of such IFN-α monotherapy, clinical trials of combination therapy using IFN-α and BCG (11) have been conducted on patients with bladder cancer. Despite some encouraging outcomes, further studies are still required for establishing the more potent, safer, and cost-effective treatment modalities.

IFN-α2b and GSP may not only help enhance IFN-α2b activity but also help cut its cost down. However, it is yet required to address how the effective concentrations (e.g., 20K or 50K IU/ml) of IFN-α2b and GSP in this in vitro study would be extrapolated to animals or actual patients. Nevertheless, several studies have already reported antitumor activity of GSP in vivo. For example, GSP was found to inhibit prostate tumor growth and angiogenesis (21) as well as breast cancer metastasis in mice (22) or enhance cytotoxic effect of doxorubicin in mice bearing Sarcorna 180 and Hepatoma 22 (23). No palpable side effects of GSP have been yet reported in these animal studies, and the LD50 of GSP in the rats has been estimated to be >5,000 mg/kg body weight (24), verifying its low toxicity. Moreover, patients with chronic pancreatitis demonstrated the symptomatic improvements, such as the reduction in both pain index and incidence of vomiting (25), with a daily dose of 200-300 mg of GSP. This also implies that GSP may have few side effects and is safe to be used in clinical practice.

In conclusion, IFN-α2b, and GSP can individually demonstrate antiproliferative effect on bladder cancer T24 cells. When they were combined, such inhibitory activity would be additively enhanced, resulting in a nearly complete growth cessation. In addition, this additive potentiation can be seen in other cancer cell types as well. The underlying mechanism of IFN-α2b/GSP-enhanced growth inhibition appears to be more likely attributed to a G1 cell cycle arrest. Therefore, specific IFN-α2b/GSP combination may provide alternative, adjuvant intravesical therapy for superficial bladder cancer.

Conflict of Interest

The authors have declared that no conflict of interest exists.
