(Dated: July 1, 2009)

We study the reduced fidelity susceptibility $\chi_r$ for an $M$-body subsystem of an $N$-body Lipkin-Meshkov-Glick model with $\tau = M/N$ fixed. The reduced fidelity susceptibility can be viewed as the response of subsystem to a certain parameter. In noncritical region, the inner correlation of the system is weak, and $\chi_r$ behaves similar with the global fidelity susceptibility $\chi_g$, the ratio $\eta = \chi_r/\chi_g$ depends on $\tau$ but not $N$. However, at the critical point, the inner correlation tends to be divergent, then we find $\chi_r$ approaches $\chi_g$ with the increasing the $N$, and $\eta = 1$ in the thermodynamic limit. The analytical predictions are perfect agreement with the numerical results.

I. INTRODUCTION

Quantum phase transition (QPT) occurs at an arbitrarily small change of the driving parameter, such as temperature. It was studied conventionally by Landau paradigm with order parameter in the frame of statistics and condensed matter physics. Recently, two quantum-information concepts, entanglement and fidelity have been investigated extensively in QPTs and are recognized to be effective and powerful in detecting the critical point. The former measures quantum correlations between partitions, while the latter measures the distance in quantum state space. Therefore, the success of them in characterizing QPTs is understood by regarding the universality of the critical behaviors itself, that is, the divergent of the correlation and the dramatic change of the ground state structure. Furthermore, as the fidelity depends computationally on an arbitrarily small change of the driving parameter, Zamardis et al. suggested the Riemannian metric tensor, while You et al. suggested the fidelity susceptibility, both focus on the leading term of the fidelity. In the following, we mainly consider the fidelity susceptibility (FS).

Until now, most efforts have been devoted to the study of the global ground state fidelity susceptibility (GFS), denoted by $\chi_g$, which reflects the susceptibility of the system in response to the change of certain driving parameter. In this work, we study the responses of a subsystem, for which we study its FS, the so-called reduced fidelity susceptibility (RFS), denoted by $\chi_r$. Some special cases have been studied in Refs. [20, 24, 27, 28], where the subsystems are only one-body or two-body, while in this paper we will study an arbitrary $M$-body subsystem. The motivation for the investigation of RFS is clear in physics. Firstly, it reveals information about the change of the inner structure for a system that undergoes QPT. Secondly, as the existence of interactions and correlations, a general quantum system is not the simple addition of its different parts, especially in the critical region, where the entanglement entropy is divergent. Therefore it is significant to investigate the behavior of the RFS, as well as the effects of entanglement on it, in both critical and noncritical regions. And our study can be viewed as a connection between the FS and the entanglement entropy.

To study this question, we consider an $N$-body Lipkin-Meshkov-Glick model (LMG) model, and study the RFS for its $M$-body subsystem. As $0 \leq \chi_r \leq \chi_g$, we consider a more useful quantity, $\eta = \chi_r/\chi_g$, and thus $\eta \in [0,1]$. We find that, the behaviors of the RFS, as well as $\eta$, are quite different in noncritical and critical regions. In noncritical region, the entanglement entropy is saturated by a finite upper bound, and the inner correlation is small, thus the RFS behaves similar with the GFS, and the ratio $\eta$ depends on $\tau = M/N$ but not $N$. However, at the critical point, the entanglement entropy tends to be divergent with the increasing of system size, and the inner correlations are very strong. Then we find the RFS approaches GFS with the increasing of $N$, and $\eta = 1$ in the thermodynamic limit for $\tau \neq 0$. These can be understood by considering the divergent of correlation in second-order QPTs, which is reflected by the entanglement entropy.

This paper is organized as follows. In Sec. II, we introduce the LMG model and give a brief review of the GFS studied in [27]. Then in Sec. III, we derive the RFS in the thermodynamic limit and obtain its divergent form in the vicinity of the critical point. Then we perform some numerical computations, and the results are in perfect agreement with our analytical prediction.

II. LMG MODEL AND GLOBAL FIDELITY SUSCEPTIBILITY

The LMG model, originally introduced in nuclear physics and has found applications in a broad range of other topics: statistical mechanics of quantum spin system \[30\], Bose-Einstein condensates \[31\], or magnetic molecules such as Mn\(_\text{12}\) acetate \[32\], as well as quantum entanglement \[33\], and quantum fidelity \[27, 28\]. It is an exactly solvable \[34, 35\] many-body interacting quantum system as well as one of the simplest to show a quantum transition in the regime of strong coupling. The quantum phase transition of this model can be described by the symmetry broken mechanism, the two phases are associated with either collective or single-particle behavior. The Hamiltonian of the LMG model reads

\[
H = -\frac{1}{N} (S_x^2 + \gamma S_y^2) - h S_z,
\]

where \(S_\alpha = \sum_{i=1}^N \sigma_\alpha^i/2 \ (\alpha = x, y, z)\) are the collective spin operators; \(\sigma_\alpha^i\) are the Pauli matrices; \(N\) is the total spin number; \(\gamma\) is the anisotropic parameter. \(\lambda\) and \(h\) are the spin-spin interaction strength and the effective external field, respectively. Here, we focus on the ferromagnetic case \((\lambda > 0)\), and without loss of generality, we set \(\lambda = 1\) and \(0 \leq \gamma \leq 1\). As the spectrum is invariant under the transformation \(h \leftrightarrow -h\), we only consider \(h \geq 0\). This system undergoes a second-order QPT at \(h = 1\), between a symmetric (polarized, \(h > 1\)) phase and a broken (collective, \(h < 1\)) phase, which is well described by a mean-field approach \[36\]. The classical state is fully polarized in the field direction \((\langle \sigma_z^i \rangle = 1)\) for \(h > 1\), and is twofold degenerate with \(\langle \sigma_z^i \rangle = h\) for \(h < 1\).

Before deriving the RFS, we give a brief review of the GFS of the LMG model that has been studied in Ref. \[27\], where the authors employed the Holstein-Primakoff transformation and derived the GFS for both phases in the thermodynamic limit,

\[
\chi \equiv \left\{ \begin{array}{ll}
\frac{N}{4\sqrt{(1-h^2)(1-\gamma)}} + \frac{\left(h^2 - \gamma\right)^2}{32(1-\gamma)^2(1-h^2)^2}, & \text{for } 0 \leq h < 1, \\
\frac{h^4}{32(1-\gamma)^2(1-h^2)^2}, & \text{for } h \geq 1.
\end{array} \right.
\]

It has been found that, when \(h < 1\), the GFS increases with \(N\) and can be viewed as an extensive quantity, however, when \(h > 1\) the GFS is saturated with an upper bound, i.e. it is intensive.

III. REDUCED FIDELITY SUSCEPTIBILITY

A. Thermodynamic limit

Now we give some basic formulas for fidelity and its susceptibility. As the subsystem is represented by a mixed state, we introduce the Uhlmann fidelity \[42\],

\[
F(\rho, \tilde{\rho}) \equiv \text{tr} \sqrt{\rho^{1/2} \tilde{\rho} \rho^{1/2}},
\]

where \(\rho \equiv \rho(h)\) and \(\tilde{\rho} \equiv \rho(h + dh)\) with a certain parameter \(h\). If \(dh\) tends to zero, the two states are close in parameter space, and their Bures distance \[41\] is,

\[
ds^2 = 2 \left[ 1 - F(\rho, \tilde{\rho}) \right].
\]

In the basis of \(\rho\), denoted by \(\{|\psi_n\rangle\}\), the Bures distance can be written as \[43\]

\[
ds^2 = \frac{1}{4} \sum_{n=1}^N p_n^2 + \frac{1}{2} \sum_{n \neq m}^N \frac{(p_n - p_m)^2}{p_n + p_m} |\langle \psi_n | d\psi_m \rangle|^2.
\]

where \(p_n\) are the eigenvalues of \(\rho\), \(N\) is the dimension of \(\rho\). As FS is the leading term of fidelity, i.e., \(F = 1 - \chi^2/2\), we can get FS for \(h\) immediately,

\[
\chi(h) = \frac{1}{4} \sum_{n=1}^N \frac{(\partial_h p_n)^2}{p_n} + \frac{1}{2} \sum_{n \neq m}^N \frac{(p_n - p_m)^2}{p_n + p_m} |\langle \psi_n | \partial_h \psi_m \rangle|^2,
\]

where \(\partial_h := \partial / \partial h\). In our study, \(\rho\) and \(\tilde{\rho}\) are just the reduced density matrices for ground states.

In the follows, the \(N\)-body LMG is divided into two parts, \(A\) and \(B\) with size \(M\) and \(N - M\), respectively. We will study the RFS for subsystem \(A\), the reduced density matrix is \(\rho_A\). This study would give a connection between the RFS and the entanglement entropy \[10\]. As we know that, the entanglement reflects the correlation among inner partitions, and our study will reveal the effects of these correlations on RFS, especially at the critical point.

Now we introduce the total spin operators for the two subsystems, \(S_A^2 = \sum_{i \in A} \sigma_i^2/2\). To describe quantum fluctuations, it is convenient to use the Holstein-Primakoff representation of the spin operators \[37\], and the first step is to rotate the \(z\) axis along the semiclassical
magnetization
\[
\begin{pmatrix}
S_x \\
S_y \\
S_z
\end{pmatrix} =
\begin{pmatrix}
\cos \theta_0 & 0 & \sin \theta_0 \\
0 & 1 & 0 \\
-\sin \theta_0 & 0 & \cos \theta_0
\end{pmatrix}
\begin{pmatrix}
\tilde{S}_x \\
\tilde{S}_y \\
\tilde{S}_z
\end{pmatrix}.
\]
(7)

As presented in [33], \(\theta_0 = 0\) for \(h > 1\) so that \(S = \tilde{S}\), and \(\theta_0 = \arccosh \ h\) for \(h \leq 1\). The Holstein-Primakoff representation is then applied to the rotated spin operators
\[
\tilde{S}_z = M/2 - a^\dagger a,
\]
\[
\tilde{S}_x = \sqrt{M} a^\dagger \sqrt{1 - a^\dagger a/M} = (\tilde{S}_+^A)^\dagger,
\]
\[
\tilde{S}_y = (N - M)/2 - b^\dagger b,
\]
\[
\tilde{S}_x = \sqrt{N - M} b^\dagger \sqrt{1 - b^\dagger b/(N - M)} = (\tilde{S}_+^B)^\dagger,
\]
where \(a (a^\dagger)\) and \(b (b^\dagger)\) are bosonic creation and annihilation operators for subsystem \(A\) and \(B\), respectively, and \(S_{z,A,B}^x = S_{z,A,B}^x + i S_{y,A,B}^x\). After this transformation, the LMG Hamiltonian is mapped onto a system of two interacting bosonic modes \(a\) and \(b\). For fixed \(\tau = M/N\), the Hamiltonian can be expanded in \(1/N\). Up to the order \((1/N)^0\), one gets \(H = NH_0^{(1)} + H_0^{(0)} + O(1/N)\) with \(H_0^{(1)} = (m^2 - 2h)/4\), where \(m = \cos \theta_0\), and
\[
H_0^{(0)} = -\frac{1 + \gamma}{4} + \mathbf{A}^\dagger \mathbf{W}^\dagger T + \frac{1}{2} \left[\mathbf{A}^\dagger \mathbf{W} (\mathbf{A})^T + \text{h.c.}\right].
\]
(9)
where \(\mathbf{A} = (a, b)\), and
\[
\mathbf{V} = \frac{2hm + 2 - 3m^2 - \gamma}{2},
\]
\[
\mathbf{W} = \frac{\gamma - m^2}{2} \sqrt{\frac{\tau}{1 - \tau}} \sqrt{\frac{1 - \tau}{\tau}},
\]
(10)
where \(\mathbb{I}\) is a 2 \(\times\) 2 identity matrix; \(m = h\) in broken phase and \(m = 1\) in symmetric phase. The bosonic Hamiltonian can be diagonalized by Bogoliubov transformation and is useful in deriving the reduced density matrix. As shown in [38, 39, 40], the reduced density matrix for eigenstates of a quadratic form can always be written as \(\rho_A = e^{-\mathcal{H}}\) with
\[
\mathcal{H} = \kappa_0 + \kappa_1 a^\dagger a + \kappa_2 (a^12 + a^22).
\]
(11)
\(\kappa_i\) \((i = 0, 1, 2)\) can be determined by using [10]
\[
\text{tr} \rho_A = 1, \quad \text{tr} (\rho_A a^\dagger a) = \langle a^\dagger a \rangle \quad \text{and} \quad \text{tr} (\rho_A a^{12}) = \langle a^{12} \rangle.
\]
(12)
where \(\langle \Omega \rangle = \langle \psi^\dagger \Omega | \psi \rangle, | \psi \rangle\) is the ground state. Then we can diagonalize \(\rho_A\) by Bogoliubov transformation. However, in this paper we will adopt another method to diagonalize \(\rho_A\), as shown in Ref. [11], \(\rho_A\) is written in the bosonic coherent state representation
\[
\langle \phi | \rho_A | \phi' \rangle = K \exp \left[ \frac{1}{4} (\phi^* + \phi') \frac{G_{++} + 1}{G_{++} + 1} (\phi^* + \phi') \right. \\
\times \exp \left[ \frac{1}{4} (\phi^* - \phi') \frac{G_{--} + 1}{G_{--} + 1} (\phi^* - \phi') \right].
\]
where \(a(\phi) = \phi(\phi); K = \sqrt{(1 + G_{++})(1 - G_{--})}\) is determined by the normalization of \(\rho_A\); \(G_{++}\) and \(G_{--}\) are Green’s functions defined as
\[
G_{++} = \langle \langle a^\dagger + a^2 \rangle^2 \rangle,
\]
\[
G_{--} = \langle \langle a^\dagger - a^2 \rangle^2 \rangle.
\]
(13)
Then \(\rho_A\) can be diagonalized by the following Bogoliubov transformation,
\[
g = \cosh \varphi a + \sinh \varphi a^\dagger = \frac{P + Q}{2} a + \frac{P - Q}{2} a^\dagger
\]
(14)
with \(PQ = 1\), \(PG_{++} = \mu Q\), and \(QG_{--} = -\mu P\). The Green’s functions can be obtained by diagonalizing the bosonic represented Hamiltonian [41],
\[
G_{++} = 1 + \frac{1}{\alpha - 1} \tau,
\]
\[
G_{--} = (1 - \alpha) \tau - 1,
\]
(15)
where
\[
\alpha = \left\{ \begin{array}{ll}
\sqrt{\frac{h - 1}{h - \gamma}} & \text{for } h \geq 1, \\
\sqrt{\frac{1 - h^2}{1 - \gamma}} & \text{for } 0 \leq h < 1.
\end{array} \right.
\]
(16)
The diagonalized \(\rho_A\) reads
\[
\rho_A = \frac{2}{\mu + 1} e^{-\varphi \xi},
\]
(17)
where the pseudoenergy \(\varepsilon = \ln [(\mu + 1)/(\mu - 1)]\) with \(\mu = \alpha^{-1/2} \sqrt{(\tau + 1)/(\tau - 1) + \alpha (1 - \tau)}\).

Now we can derive the RFS, of which the first term involves only the eigenvalues of \(\rho_A\), and the second term involves both the eigenvalues and the eigenvectors. The eigenvectors of \(\rho_A\) is the number state \(|n\rangle; g^\dagger g |n\rangle = n |n\rangle\), and the term \(|\langle n| \partial_m n \rangle|^2 = |\langle n| \partial_m n \rangle|^2\) can be calculated by using
\[
|\langle n| \partial_m n \rangle|^2 = \frac{|\langle n| \partial_m n \rangle|^2}{(m - n)^2}.
\]
(18)
Then we write the RFS explicitly,
\[
\chi_r (h, \gamma, \tau) = \frac{(\partial_h \mu)^2}{4 (\mu^2 - 1)} + \frac{(\mu \partial_h \phi)^2}{\mu^2 + 1} + \frac{N \tau}{4 \mu} (\partial_h \theta_0 \exp \varphi)^2,
\]
(19)
where \(\varphi = \arctanh [(\mu - G_{++})/(\mu + G_{++})]\), \(\theta_0 = \arccosh h\) for \(h \leq 1\) and \(\theta_0 \equiv 0\) for \(h > 1\). Thus the last term of the above expression only takes effect in the broken phase. We emphasize that, in the broken phase \(h < 1\), we should perform a rotation [7] at first.
\[ \chi_r (h, \gamma, \tau) = \begin{cases} \chi + \frac{N\tau}{4G^{++}(1-h^2)} & \text{for } 0 \leq h < 1, \\ \chi & \text{for } h \geq 1, \end{cases} \]

where

\[ \chi = \frac{(\partial_h \mu)^2}{4(\mu^2 - 1)} + \frac{\mu^2}{4(\mu^2 + 1)} \left[ \partial_h \ln \left( -\frac{\mu}{G^{++}} \right) \right]^2. \]

In the vicinity of the critical point, the RFS diverges as

\[ \chi_r / N \propto (1-h)^{-1/2}, \quad \text{for } 0 \leq h < 1, \]

\[ \chi_r \propto (1-h)^{-2}, \quad \text{for } h \geq 1, \]

and this is the same with \( \chi_0 \). Additionally, we show the entanglement entropy \( \mathcal{E} = -\text{tr}(\rho \ln \rho) \) that was derived in \([10,11]\),

\[ \mathcal{E} = \frac{\mu + 1}{2} \ln \frac{\mu + 1}{2} - \frac{\mu - 1}{2} \ln \frac{\mu - 1}{2} + x \ln 2. \]

where \( x = 1 \) when \( h < 1 \) and \( x = 0 \) when \( h > 1 \), the \( \ln 2 \) term comes from the two-fold degeneracy of the ground state in the broken phase, and this degeneracy is lifted for finite \( N \). The entanglement entropy diverges as \( (1/4) \ln |h-1| \) around the critical point, and is nearly independent with \( N \) in noncritical region.

### B. Finite size cases

To perform numerical computations, we should derive the reduced density matrix for \( \rho_A \) in finite size case. The LMG model is of high symmetry in interaction, and the ground state which is the superposition of the Dick states lies in the \( J = N/2 \) section.

![FIG. 1: RFS as a function of \( h \) at \( \gamma = 1/2 \) and \( \tau = 1/2 \). The peaks approach the critical point and become sharper and sharper with the increasing of \( N \).](image1)

![FIG. 2: A comparison between \( \eta \) (a) and \( \mathcal{E} \) (b) as a function of \( h \) at \( \gamma = 1/2 \), \( \tau = 1/2 \) for various system sizes. At the critical point, \( \eta \) tends to 1 while \( \mathcal{E} \) is divergent.](image2)
\[
(p_A)_{p,q} = \sum_{m=0}^{N} C_m C^*_m \sqrt{\mathcal{H}(p;2J,2J_A,m)} \times \sqrt{\mathcal{H}(q;2J,2J_A,q + m - p)}.
\] (28)

By using the exact diagonalization method, the RFS as a function of \( h \) for fixed \( \tau \) is computed and shown in Fig. (1). As one can see that, the peaks of the RFS approach the critical point and become sharper and sharper with the increasing of \( N \). The RFS in the symmetric phase \((h > 1)\) has an upper bound, however, in the broken phase \((h < 1)\) the RFS increases with the total spin number \( N \). Thus we address that, the RFS is extensive in the broken phase, in which the LMG model behaves like a single particle. This is similar with the GFS [27].

As \( 0 \leq x_t \leq x_g \), we will focus on a more useful quantity \( \eta(\tau, h) \equiv x_t(\tau, h, \gamma, \tau)/x_g(\tau, h, \gamma) \) and study its properties in critical and noncritical regions. With Eqs. (2), (19), we find that in the thermodynamic limit

\[
\lim_{\eta \to 1} \eta(\tau, h) = 1,
\] (29)

for any non-vanishing \( \tau \). To verify our prediction, we show the analytical and numerical results in Fig. (2). As one can see that, at the critical point, the RFS approaches the global one, i.e. \( \eta \) tends to 1, and at the same time, the entanglement entropy, i.e. the inner correlation between subsystems \( A \) and \( B \), is divergent with the increasing of \( N \). When \( h \) is away from the critical region, the inner correlation decreases dramatically, and then \( \eta \) depends on \( \tau \) but not the total system size \( N \) as shown in Fig. (3).

As demonstrated in Ref. [28], when there are no correlations between partitions of a system, for example an \( N \)-body system represented by a product state that reads

\[
|\psi(h)\rangle = \bigotimes_{i=1}^{N} |\phi_i(h)\rangle,
\] (30)

if we denote a one-body reduced fidelity as \( F_\tau \), the relation between the global and the reduced fidelities is

\[
F_g(h, \delta) = \prod_{i=1}^{n} F_\tau^i(h, \delta).
\] (31)

and thus we have \( \chi_g = \sum_{i=1}^{N} \chi_i^r \), moreover, if the system is of translation symmetry, we have \( \chi_g = N \chi_r \). If there is entanglement between partitions, we have no such results, especially in the critical point, the entanglement is divergent, and then \( \chi_g/\chi_r \equiv 1 \) in the thermodynamic limit. This is some kind of effect of the inner correlations on the susceptibility of the system states. However, we address that our results are based on a high-dimension model, actually there are interactions between any two particles in the LMG model. We think it is deserved to study the RFS for a contiguous block in a low-dimension model, for example, the \( XY \) model in which the interaction is just between neighboring sites. Thus the correlation between a block and its complementary part takes effect only on the boundary, and the results for \( \eta \) maybe different.

\[ \text{Fig. 3: } \eta \text{ as a function of } \tau \text{ with } \gamma = 1/2, \text{ at } h = 0.6 \text{ (a), } 0.9 \text{ (b), } 1.0 \text{ (c) and } 1.1 \text{ (d). We see that } \eta \text{ is nearly independent of } N \text{ when } h \text{ is away form the critical region.} \]

\[ \text{IV. CONCLUSION} \]

In conclusion, we derive the RFS analytically in the thermodynamic limit for a fixed \( \tau \). To analyze the effects of the inner correlations on the RFS, we study the ratio \( \eta = \chi_r/\chi_g \) combined with the entanglement entropy in both critical and noncritical regions. Our results give a clear picture for understanding the effects of correlations on the response. In the critical region, with the increasing of \( N \), the entanglement entropy tends to be divergent and \( \eta \) approaches 1, while in the thermodynamic limit, \( \eta \equiv 1 \) for \( \tau \neq 0 \). This indicates that, the sensitivity of the subsystem is equal to the global one. In noncritical region, the RFS behaves similarly with the GFS, and \( \eta \) depends on \( \tau \) but not \( N \).
