Supporting Information

ABSTRACT: Solar light-activated photocatalyst nanoparticles (NPs) are promising environment-friendly low cost tools for water decontamination, but their dispersion in the environment must be minimized. Here, we propose the incorporation of TiO2-NPs (also in combination with graphene platelets) into highly biocompatible hydrogels as a promising approach for the production of photoactive materials for water treatment. We also propose a convenient fluorescence-based method to investigate the hydrogel photocatalytic activity in real time with a conventional fluorimeter. Kinetics analysis of the degradation profile of a target fluorescent model pollutant demonstrates that fast degradation occurs in the matrix bulk. Fluorescence anisotropy proved that small pollutant molecules diffuse freely in the hydrogel. Rheological and scanning electron microscopy characterization showed that the TiO2-NP incorporation does not significantly alter the hydrogel mechanical and morphological properties.

INTRODUCTION

Pollution is one of the most important unsolved problems that nowadays affects our society. Photocatalytic degradation of water pollutants is a very attractive strategy to convert contaminants into harmless compounds by using eco-friendly materials. This approach is typically based on nanostructured photocatalysts, which are activated by solar light and use the absorbed energy to produce reactive chemical species, starting from water and oxygen (as schematized in Figure 1), and are able to degrade organic pollutants. Most effective photocatalysts are metal-oxide semiconductors (such as ZnO, FeO3, and WO3) and, in particular, titanium dioxide nanoparticles (TiO2-NPs), in their anatase form, which have been widely used for a range of applications, including self-cleaning, surface sterilization, and air and water purification. Advantageous features of TiO2-NPs are the excellent stability in water, large-scale availability, and low cost. TiO2-NPs also show low toxicity, nevertheless the recent concerns about the still partially unpredictable risks related to the impact of nanomaterials on the environment and human health, as a defensive approach to minimize their dispersion in the environment. Incorporation of TiO2-NPs in highly biocompatible, macroscopic matrices that preserve the photocatalytic activity of the semiconductor NPs is hence a fundamental challenge in the design of new materials for photocatalysis. As a fundamental feature, these matrices should present (i) a high water content because water plays an essential role in the photocatalytic process (see Figure 1), (ii) good permeability to small molecules (pollutants), and (iii) good transparency to solar light.

In the last few years, we focused our research on the use of small pseudopeptides to form supramolecular hydrogels with specific properties, tailored to suit the applications of the...
produced hydrogels. Hence, we could obtain hydrogels of different strengths, pH values, and transparencies. These properties are not all necessarily needed for a given application. In this paper, we want to describe the preparation of transparent hydrogels and their application for photodegradation.

We recently reported the preparation of hydrogels by slow pH variation of a water solution of Fmoc-L-Tyr-D-Oxd-OH [Fmoc = fluorenylmethyloxycarbonyl; Tyr = tyrosine; and D-Oxd = (4R,5S)-4-carboxy-5-methyl-oxazolidin-2-one] (F in Figure 2), and we compared their properties with the gelator in 0.5% concentration, TiO2-NPs (0.2 mg/mL), and glucono-δ-lactone; (iii) 3 (H-TG) is prepared following the same procedure used for 2 (H-T), but replacing TiO2-NPs with TiO2-NPs/graphene.

Before testing the hydrogels based on Fmoc-L-Tyr-D-Oxd-OH for the photocatalytic applications, we investigated the effect of TiO2-NPs or TiO2-NPs/graphene on their mechanical and morphological characteristics. Rheological analyses have been performed to evaluate the viscoelastic properties of hydrogels 1 (H), 2 (H-T), and 3 (H-TG) in terms of storage and loss moduli (G′ and G″, respectively) (Table 1 and Figures S1 and S2).

### RESULTS AND DISCUSSION

#### Hydrogel Preparation and Characterization.
For the hydrogel preparation, we used the pH change method. This method relies upon the enhanced solubility of Fmoc-Tyr-Oxd-OH at basic pH, followed by a slow decrease of pH by the addition of glucono-δ-lactone. We prepared three different samples of hydrogels: (i) hydrogel 1 (H) contains only the gelator Fmoc-L-Tyr-D-Oxd-OH in 0.5% (w/w) concentration and glucono-δ-lactone; (ii) hydrogel 2 (H-T) contains the gelator in 0.5% concentration, TiO2-NPs (0.2 mg/mL), and glucono-δ-lactone; (iii) 3 (H-TG) is prepared following the same procedure used for 2 (H-T), but replacing TiO2-NPs with TiO2-NPs/graphene.

Although the hydrogels are characterized by a “solidlike” behavior, that is, the storage modulus is approximately an order of magnitude higher than the loss component, these hydrogels do not show very high G′ values because of the very low concentration of the gelator, required for obtaining good transparency. The results also pointed out that although the introduction of TiO2-NPs or TiO2-NPs/graphene partially affects the hydrogel properties, as in both cases, G′ decreases. This effect is more evident for hydrogel 3 (H-TG). Nevertheless, frequency sweep analysis (Figure S2) pointed out that for all obtained hydrogels, both G′ and G″ were almost independent of the frequency in the range from 0.1 to 100 rad·s⁻¹ (always with G′ > G″), confirming the “solidlike” rheological behavior of the hydrogels and hence the stability of the hydrogel structure required for the photocatalytic application.

Step-strain experiments were performed to check the thixotropic behavior of 1 (H), 2 (H-T), and 3 (H-TG) on the molecular level. Strain values within and above the LVE region were consecutively applied to the hydrogels, which lose their “solidlike” behavior (G′ < G″) when the strain is applied above their LVE region and quickly go back to a “solidlike” state (G′ > G″) if the strain is applied in the LVE region of the hydrogels (Figure 3). The three hydrogels show a thixotropic behavior, even though the G′ and G″ values of the graphene-doped hydrogel 3 (H-TG) are lower than the 1 (H) and 2 (H-T) G′ and G″ values.

More information on the nature of hydrogels 1 (H), 2 (H-T), and 3 (H-TG) was obtained by scanning electron microscopy (SEM) analysis of the corresponding aerogels obtained from the corresponding hydrogels by freeze-drying these samples (Figure 4). These aerogels show a different morphology, but they are all characterized by complex patterns with a rough orientation. Moreover, in aerogel 3 (H-TG) (Figure 4C and magnification), we can notice the presence of some small aggregates responsible for the formation of a less homogeneous hydrogel, in agreement with the results obtained from the rheological experiments.

#### Photodegradation Experiments.
As mentioned, here, we propose an experimental approach based on fluorescence detection for investigating the photodegradation of a target molecule in the gel. As a main difference with respect to other...
methods based on fluorescence, we propose to use the same excitation beam and the same excitation wavelength for both photoactivating the photocatalyst TiO₂ and exciting the target fluorophore RhB (see Figure 2). As a main advantage, this approach allows the continuous real-time detection of the target dye concentration during the process using a conventional fluorimeter equipped with a 150 W xenon lamp as an excitation source.

To select a suitable irradiation wavelength, we analyzed the absorption spectra of hydrogel 1 (H) of the TiO₂-NPs (0.2 mg/mL) and RhB (1.0 μM) in a cuvette with a 0.5 cm optical path (spectra are shown in Figure 5). These spectra demonstrate that it is possible to excite simultaneously the TiO₂-NPs and RhB upon irradiation in the UV spectral region when they are incorporated in the hydrogel (as sketched in Figure 2).

In fact, as foreseen, the hydrogel presents an edge of absorption around 310 nm because of the characteristic absorption spectra of the Fmoc chromophore that is present in the gelator structure. The hydrogel transmittance is T > 60% for wavelength λ > 320 nm, and hence the photocatalyst TiO₂-NPs incorporated in the hydrogel in 1 (H) can be efficiently excited at 340 ± 10 nm using the fluorimeter excitation beam as an irradiation source (the spectral profile is shown in Figure 5).

Additionally, under these excitation conditions, RhB absorbs a minor fraction of the excitation light, and its fluorescence can be exploited as a diagnostic signal to follow the photo-degradation of this dye during the photocatalytic experiments.

To investigate the TiO₂ photocatalytic activity in the hydrogel, we prepared three samples like 1 (H), 2 (H-T), and 3 (H-TG), all containing a small concentration (1.0 μM) of RhB. For clarity, these samples will be referred as 4 (HR), 5 (HR-T), and 6 (HR-TG). Hydrogel rheological properties were not affected by the presence of small concentrations of RhB (1.0 μM) in the hydrogels.

Results, reported in Figure 6, show that there is a strong decrease in RhB emission during the first hour of irradiation in the case of 5 (HR-T) and 6 (HR-TG). By contrast, in the reference hydrogel 4 (HR), the fluorescence signal decreases only by about 20% during the first 10 min (600 s), and then it reaches a plateau. Hence, as the fluorescence intensity is proportional to the fluorophore concentration, under these experimental conditions we can gather that after 60 min of irradiation, the RhB concentration in the reference sample 4 (HR) is still 80% of the initial one, whereas the dye is completely degraded in the TiO₂-containing sample 5 (HR-T) and a residual 25% survived in 6 (HR-TG). These results clearly demonstrate that (i) the TiO₂-NPs photodecompose

Figure 3. Values of storage moduli G’ (black) and loss moduli G” (red) recorded during a step-strain experiment performed on (A) hydrogel 1 (H), (B) hydrogel 2 (H-T), and (C) hydrogel 3 (H-TG).

Figure 4. (A) SEM image of a sample of aerogel obtained by freeze-drying a sample of hydrogels 1 (H), (B) SEM image of a sample of aerogel obtained by freeze-drying a sample of hydrogels 2 (H-T), and (C) SEM image of a sample of aerogel obtained by freeze-drying a sample of hydrogels and 3 (H-TG) prepared with Fmoc-L-Tyr-D-Oxd-OH 0.5% concentration. In the inset, a magnification view of aerogel film fragments.

Figure 5. Absorption spectrum of hydrogel 1 (H) (black line) of the TiO₂-NPs (0.2 mg/mL, red line) and RhB (1×20, 1 μM, green line). Fluorescence spectrum of RhB (filled yellow) and spectrum of the irradiation source (filled cyan). Inset: photographs of samples of hydrogels 1 (H), 2 (H-T), and 3 (H-TG) (from left to right, respectively) prepared with gelator Fmoc-L-Tyr-D-Oxd-OH in 0.5% concentration.
Figure 6. Fluorescence intensity at 585 nm of RhB as a function of irradiation time (λ_{exc} = 340 nm) in sample 4 (HR), 5 (HR-T), and 6 (HR-TG).

Figure 7. Fluorescence spectra (λ_{exc} = 530 nm) of RhB in sample 4 (HR) (black line), 5 (HR-T) (red line), and 6 (HR-TG) (green line) and fluorescence anisotropy of the same samples: black, red, and green triangles, respectively.

Going into more detail, a simple parameter suitable to quantify the rate of the photodegradation process is the half-life \( t_{1/2} \), which is defined as the irradiation time at which the concentration value of the reactant (RhB) becomes half of the initial one. The half-life \( t_{1/2} \) of RhB corresponds to 12 and 23 min of irradiation for 5 (HR-T) and 6 (HR-TG), respectively.

To go into more details of the photodegradation kinetics, we analyzed the kinetics traces of Figure 6 according to a (pseudo) first-order model (see the Supporting Information). From the data analysis, we obtain values of the rate constant \( k \) = 8.0 ± 0.1 \times 10^{-4} \text{s}^{-1} and \( k \) = 4.0 ± 0.1 \times 10^{-4} \text{s}^{-1} for 5 (HR-T) and 6 (HR-TG), respectively. This result further confirms that the presence of graphene in the hydrogel apparently causes a decrease in the TiO_{2}-NP photocatalytic activity.

Indeed, SEM and rheological analyses clearly indicate that graphene affects the matrix morphology and causes a homogeneity decrease of the TiO_{2}-NP dispersion (see the Supporting Information); this alteration is the actual reason for the decreased photocatalytic activity of 6 (HR-TG) when compared to 5 (HR-T).

As far as the mechanism of photodegradation is concerned, the observed (pseudo) first-order kinetics is consistent with the Langmuir–Hinshelwood model, which is the most representative in describing the kinetic degradation of xanthene dyes as RhB in heterogeneous photocatalysis. This model takes into consideration the contribution of both dye adsorption on the photocatalyst surface and dye diffusion.

In view of future applications, it is very important to understand whether, in the hydrogel, the target molecules RhB can freely diffuse or they are bound either to the gelator fibers or to the TiO_{2}-NPs. Free diffusion of the pollutant moiety is in fact essential for the development of a material suitable for continuous recyclable materials for water decontamination.

We hence investigated the interactions between the target dye molecules and the microenvironment by steady-state and time-resolved fluorescence spectroscopies, using fluorescence anisotropy to measure the local mobility of RhB in 4 (HR), 5 (HR-T), and 6 (HR-TG).

Quenching of RhB fluorescence has been reported to occur upon absorption on TiO_{2} or onto the honeycomb carbon structure of graphene.\(^{51,52}\) Hence, we recorded and compared the fluorescence emission and excitation spectra of RhB (λ_{exc} = 530 nm) of 4 (HR), 5 (HR-T), and 6 (HR-TG). On the basis of the fluorescence spectra, shown in Figure 7, we concluded that no quenching of the fluorescence of RhB could be observed in 5 (HR-T) and 6 (HR-TG).

This conclusion was further supported by time-resolved fluorescence measurements. Excited-state lifetimes were measured by time-correlated single photon counting. Fluorescence decays recorded for RhB in 4 (HR), 5 (HR-T), and 6 (HR-TG) were fitted with a single exponential model to give excited-state lifetimes of 3.4, 3.7, and 3.6 ns, respectively. These values match with the lifetime of the fluorophore in water solution, confirming that no quenching of the fluorescence of the target dye occurs in 4 (HR), 5 (HR-T), and 6 (HR-TG).\(^{48,53,54}\)

As mentioned, fluorescence anisotropy \( r \) (dimensionless) measurements allow to determine the rotational mobility of a fluorophore in a given environment. Values of \( r \) close to 0.4 were reported for rhodamine molecules in the case of strongly hindered rotation,\(^{55,56}\) whereas the same molecules have an \( r \) very close to 0 when free to diffuse in poorly viscous solvent such as water.

Fluorescence anisotropy spectra of RhB in 4 (HR), 5 (HR-T), and 6 (HR-TG) are shown in Figure 7 (triangles); in all three cases, the anisotropy around the maximum fluorescence is very low (0.02–0.03) and similar to the value measured in pure water. This result confirms that the dye molecules can diffuse fast in the hydrogel (hence, the diffusion time is much shorter than the excited-state lifetime) and are dissolved in the hydrogel water channels rather than adsorbed on the gelator fibers.

**CONCLUSIONS**

In this paper, we reported the incorporation of TiO_{2}-NPs (also in combination with graphene platelets) into highly biocompatible hydrogels, whose properties have been analyzed by rheological and SEM analyses.

These hydrogels show a high water content and good transparency to solar light, and they degrade a pollutant model molecule with good efficiency upon semiconductor NP irradiation.

Interestingly, our experiments demonstrate that light penetrates inside the hydrogel and that photodegradation occurs in the bulk of the material. This important result was achieved by optimizing the composition and the methodology of production of the hydrogel to avoid sedimentation and segregation of the TiO_{2}-NPs (as demonstrated by the SEM analysis).

We also proved that while photodegradation of the target molecule (pollutant model) efficiently occurs upon irradiation, the photogenerated reactive species does not alter the matrix.
properties: rheology of the hydrogel, in fact, is not modified either by the incorporation of the photocatalysts or upon their irradiation.

Finally, we investigated the actual mobility of the pollutant molecules in the hydrogel on the microscopic level by steady-state and time-resolved fluorescence anisotropy spectroscopies. Our results demonstrated that these molecules are not absorbed either on the hydrogel fibers or on the TiO2-NPs, suggesting that pollutant molecules are rather solubilized in the hydrogel water channel. This result is very important in view of the development of photocatalytic water-permeable materials for continuous decontamination of water in fluxing systems.

**EXPERIMENTAL SECTION**

**Materials.** All chemicals and solvents were purchased from Sigma-Aldrich, VWR or Iris Biotech and were used as received. Acetonitrile was distilled under an inert atmosphere before use. Milli-Q water (Millipore, resistivity = 18.2 mΩ·cm) was used throughout.

**Synthesis of Fmoc-L-Tyr-D-Oxd-OH.** The compound was synthesized from D-Thr and Fmoc-L-Tyr(β-Bu)-OH following a multistep procedure in solution, reported in ref 24.

**Hydrogel Preparation.** A portion of Fmoc-L-Tyr-D-Oxd-OH (5 mg) was placed in a test tube (diameter: 8 mm); then Milli-Q water (0.97 mL) and a 1 M aqueous NaOH (1.3 equiv) were added; and the mixture was stirred until sample dissolution. Finally, we added 1.4 equiv of glucono-δ-lactone, and the mixture was left still for 16 h at room temperature. For more details, see Scheme S1.

**Aerogel Preparation.** Some samples of hydrogels 1–3 were freeze-dried using a BENCHTOP Freeze Dry System LABCONCO 7740030 with the following procedure: The hydrogel was prepared into an Eppendorf test tube at room temperature. After 16 h, the samples were deepened in liquid nitrogen for 10 min and then freeze-dried for 24 h in vacuo (0.2 mBar) at −50 °C.

**Hydrogel Characterization. Morphological Analysis.** Scanning electron micrographs of the samples were recorded using a Zeiss EP EVO 50 field emission gun scanning electron microscope. Conditions: EHT = 20 keV — variable pressure: 100 Pa—images in secondary electrons.

**Rheology.** Rheology experiments were carried out on an Anton Paar rheometer MCR 102 using parallel plate configuration (25 mm diameter). Experiments were performed at a constant temperature of 23 °C controlled by the integrated Peltier system and a Julabo AWC100 cooling system.

**Ultraviolet—Visible (UV—Vis) Absorption Spectra.** UV—vis absorption spectra (range 200–800 nm) were collected by using an optical path of 0.5 cm cuvette at 25 with a Cary 300 UV—vis double beam spectrophotometer, having an empty cuvette as a reference.

**Steady-State and Time-Resolved Fluorescence Spectroscopy and Fluorescence Anisotropy.** Fluorescence spectra were collected with an Edinburgh FLS920 fluorimeter equipped with a photomultiplier Hamamatsu R928P, and the samples were analyzed in disposable cuvettes with an optical path length of 0.5 cm. Emission spectra: $\lambda_{\text{exc}}$ = 530 nm; $\lambda_{\text{em}}$ = 540–700 nm. Excitation spectra: $\lambda_{\text{exc}}$ = 330–600 nm, $\lambda_{\text{em}}$ = 620 nm. Fluorescence anisotropy: $\lambda_{\text{exc}}$ = 530 nm; $\lambda_{\text{em}}$ = 550–650 nm.

**Photodegradation Experiments.** The kinetic analysis was carried on by continuously monitoring the degradation of RhB acquiring the fluorescence spectra with a Horiba FluoroMax-4 spectrophotometer upon excitation/irradiation at 340 nm (10 nm slits). Experimental parameters are reported in detail in Scheme S2.
