ABSTRACT

We present mid-infrared Spitzer-IRS spectroscopy of the prototype WN star EZ CMa (HD 50896, WN4b). Numerous stellar wind lines of HeII are revealed, plus fine-structure lines of [NeIII] 15.5 m and [OIV] 25.9 m. We carry out a spectroscopic analysis of HD 50896 allowing for line blanketing and clumping, which is compared to the mid-IR observations. We make use of these stellar properties to accurately derive Ne/He=1.2−1.8×10^{-5} and O/He=4.2−4.8×10^{-5} by number, for the first time in an early WN star. In addition, we obtain N/C∼40 and N/O∼50 by number, values in perfect agreement with current predictions for rotating massive stars at the end of interior hydrogen burning. Subject headings: techniques: spectroscopic — stars: individual (HD 50896) — stars: atmospheres — infrared: stars

1. INTRODUCTION

Wolf-Rayet (WR) stars are descended from the most massive O stars (M_{init} > 25 M_{\odot}), and shed core-processed material in thick, line-driven winds at such prodigious rates (typically 10^{-5}−10^{-4} M_{\odot} yr^{-1}) as to affect the evolution of the core and thus the lifetime of the star, prior to ending in a supernova explosion (Meynet & Maeder 2003). The prototype Wolf-Rayet star EZ CMa (HD 50896 = WR 6 in the catalogue of van der Hucht 2001) has been studied extensively at nearly all wavelengths accessible with ground-based facilities and space observatories, to understand the extreme stellar wind properties of these rare massive stars, and how they interact with their local environment.

At infrared wavelengths, the continuum opacity is principally determined by free-free scattering of electrons from helium ions, and the emergent radiation originates in the outer layers of the wind where the asymptotic velocity is reached (e.g., Hillier et al. 1983). These layers are also where critical electron densities and temperatures are reached to form fine structure lines of Ne, O, S, and other elements, that are instrumental in testing evolutionary model predictions of the surface abundances during different core burning stages.

Elemental abundances obtained from the fine structure lines depend on the stellar parameters, particularly the mass-loss rate, which is sensitive to the degree of clumping in the wind. The role played by mid-infrared spectra, in conjunction with UV, optical, and near-IR spectroscopy, has been demonstrated for a few WN and WC stars observed with the SWS (Morris et al. 2000; Dessart et al. 2000). Only the brightest WR stars could be observed with the SWS, for sensitivity reasons, and observations of only five WR stars produced spectra of suitable quality for modelling beyond 4.5 m.

In this Letter we present Spitzer-IRS spectra of the prototype early WN star EZ CMa. We carry out an analysis of the ultraviolet to mid-IR spectroscopy, revealing stellar and wind parameters, with which Ne/He and O/He abundance ratios are determined. Comparisons with theoretical expectations are presented.

2. OBSERVATIONS

EZ CMa was observed with the Spitzer InfraRed Spectrometer (described by Houck et al. 2004) on 11 November 2003, during the Science Verification phase, using all four of the IRS modules. The data were acquired with the Spectral Mapping AOT, with the star observed at 3 to 5 discrete positions along the lengths (cross-dispersed axes) of the slits. The 10 − 37.5 m data presented in this paper are from the Short and Long High (SH and LH) resolution modules (R = \lambda/\Delta\lambda \approx 700), and 5.3 − 10 m data are from the Short Low (SL) module (R \approx 70−120), using exposure times that should produce continuum signal-to-noise (S/N) ratios of around 100 in the high resolution spectra, and 200−250 in the low resolution spectra. The basic calibrations were automatically carried out in the SSC pipeline, version S9.5, and then spectra were extracted and coadded interactively, using the offline pipeline.

Our analysis also makes use of archival Infrared Space Observatory (ISO) Short Wavelength Spectrom-
The principal wind features. The majority of mid-IR spectra are due to wind lines of He II, primarily the leading member in each series from He II (7-6) at 3.09 μm to (15–14) at 34.6 μm. In addition to these, we observe fine-structure lines of [O IV] 25.9 μm and [Ne III] 15.5 μm, the latter blended with He II 15.47 μm (15–13). There is no evidence for [S IV] 10.5 μm in HD 50896. The observed feature is well reproduced by a weak blend of He II 10.46 μm (21–15) and 10.50 μm (24–16) in our synthetic spectrum.

3. SPECTROSCOPIC ANALYSIS OF HD 50896

3.1. Technique

To date, the majority of spectroscopic analyses of WN stars have been carried out using non-LTE models that did not account for metal line blanketing or clumping (e.g. Crowther et al. 1995, Hamann et al. 1995). In only a few cases have clumped, metal line blanketed models been applied to individual stars (e.g. Schmutz 1997, Morris et al. 2000, Dessart et al. 2000, Herald et al. 2001). Such effects need to be taken into account in order to determine the fundamental parameters of WR stars (Crowther 2003).

For the present study of HD 50896, we employ CMFGEN (Hillier & Miller 1998), which solves the transfer equation in the co-moving frame subject to statistical and radiative equilibrium, assuming an expanding, spherically-symmetric, homogeneous and static atmosphere, allowing for line blanketing and clumping. The stellar radius ($R_*$) is defined as the inner boundary of the model atmosphere and is located at Rosseland optical depth of ~20 with the stellar temperature ($T_*$) defined by the usual Stefan-Boltzmann relation. Consequently, the stellar radius is much smaller than the radius of the assumed velocity law.

Our approach follows previous studies (e.g. Crowther et al. 1995), such that diagnostic optical lines of He I (λ5876), He II (λ4686) plus the local continuum level allow a determination of the stellar temperature, mass-loss rate and luminosity. We were unable to employ solely mid-IR diagnostics since the IRS spectrum of HD 50896 is dominated by lines of He II, with He I weak or blended.

Our final model atom contains H, He, C, N, O, Ne, Mg, Si, P, S, Cl, Ar, Ca, Cr, Mn, Fe and Ni. In total, 1186 super levels, 4462 full levels and 45,485 non-LTE transitions are simultaneously considered. We assume hydrogen is absent, such that helium makes up 98% of the atmosphere. CNO abundances are varied until an optimal fit is achieved. In contrast with nitrogen and carbon, the abundance of oxygen in WN stars has proven to be rather challenging (Hillier 1988). The reason is that oxygen has a much more complicated ionization stratification in their inner winds, plus diagnostic lines are located in rather observationally inaccessible regions, typically 2800–3400 Å. Consequently we set oxygen (and neon) abundances from the fine-structure analysis. Other elements are fixed at Solar values (Grevesse & Sauval 1998; Asplund et al. 2004).

We adopt a standard form of the velocity law, $v(r) = v_\infty (1 - R_*/r)^\beta$, where $\beta=1$. In contrast, Schmutz (1997) solved the hydrodynamical equation for outer wind and obtained $\beta \sim 3$ with reference to the core radius. A terminal wind velocity, $v_\infty$, of 1860 km s$^{-1}$ is obtained from the mid-IR fine structure line of [O IV] 25.9 μm. For comparison, Prinja et al. (1990) obtained 1720 km s$^{-1}$.
from UV observations of the P Cygni C IV 1550Å line, whilst Schmutz (1997) derived 2060 km s\(^{-1}\) from a fit to He I 1.083μm.

The mass-loss rate is actually derived as the ratio \(M/\sqrt{T}\), where \(f\) is the volume filling factor that can be constrained by fits to the electron scattering wings of the helium line profiles (following Hillier 1991). We conclude \(f \sim 0.1\), and can definitely exclude homogeneous mass-loss in HD 50896. In addition, the mid-IR continuum slope also reacts to different filling-factors.

3.2. Spectroscopic Results

We compare our synthetic model with far-UV, near-UV, optical, near-IR and mid-IR spectrophotometry (dereddened by E(B-V)=0.10 mag) in Fig. 2. Overall the agreement between the spectral features and continuum are excellent from 0.09–37μm, with few major exceptions. For helium, all lines are reproduced better than 20%, with the exception of a few mid-IR lines, namely He II 3.091μm (7-6), 13.12μm (11-10) and 22.17μm (13-12). Since fine-structure lines are not included in our synthetic spectrum, it is apparent that [Ne III] is a non-negligible contributor to the 15.5μm feature, the 25.9μm line is dominated by [O IV] and there is no obvious identification for the lines at 20.7μm or 36.6μm (the latter is not [Ne III] 36.01μm).

The stellar parameters derived for the WN4b star are presented in Table 1. We estimate elemental abundances of N/He=2×10\(^{-3}\) and C/He=5×10\(^{-5}\) by number. Hillier (1988) previously estimated N/He≤4×10\(^{-3}\), N/C≈14 and O/N≤3 for EZ CMa, the only previous study to attempt CNO abundance determinations.

The only recent study of EZ CMa allowing for blanketing and wind clumping was by Schmutz (1997), whose results we also include in Table 1. Schmutz (1997) approached the incorporation of line blanketing in a different manner from the present approach. A Monte Carlo sampling technique was adopted, allowing for the effect of a much more thorough line opacity at the expense of full consistency in the radiative transfer problem, via the use of approximate ionization and excitation for metal species. In addition, Schmutz adopted a He II Lyα 3033 photon loss mechanism with a particular parameter. Such a mechanism is intrinsic to the present analysis without the requirement of a parameterization, providing spectral lines adjacent to He II λ3037 are accounted for in the calculation. Consequently the following metal lines within ~100 km s\(^{-1}\) of Lyα are included – O iii λ303.70, 303.80, Ni vi λ303.71, Mn vi λ303.72, Ca v λ303.74, Cr v λ303.82, Cr vi λ303.84 and Fe v λ303.91.

Agreement between the two approaches is reasonable, given the differences in approach and choice of diagnostics. In both solutions, stellar luminosities (and hence bolometric corrections) are significantly higher than previous non-LTE studies (e.g. Hamann et al. 1995), although Schmutz (1997) obtained a rather higher bolometric luminosity, due to a combination of his photon loss mechanism and more complete line opacity, whilst clumping corrected mass-loss rates are much lower. Consequently, the derived momentum ratio is found to be \(Mv_\infty/(L/c) = 7\), versus 30–70 in earlier studies. The agreement in mass-loss rate is consistent with the claimed precision of 0.1 dex achieved by Schmutz (1997), of relevance to the determination of elemental abundances to follow.

3.3. Elemental Abundances: Neon and Oxygen

We present the fine-structure lines of [Ne III] 15.5μm and [O IV] λ25.9μm in Fig. 3 including the predicted fractional contributions from [Ne III] and [O IV] (dotted lines) obtained from, respectively, the red line profile of [Ne III] which does not overlap with He II (15–13), and the non-LTE predicted He II (23–19) strength. The observed line fluxes of each blend is presented in Table 2.

Sources of atomic data are given in Dessart et al. (2000) for [Ne III], and Hayes & Nussbaumer (1983) and Blum & Pradhan (1992) for [O IV]. We have determined elemental abundances for these ions using the numerical techniques introduced by Barlow et al. (1988), and adapted to account for a clumped wind by Dessart et al. (2000) and Morris et al. (2000). With regard to clumping, we admit that the volume filling factor in the outer wind may be considerably different than that derived from optical and near-IR recombination lines (Runacres & Owocki 2002).

The numerical expression for the ion number fraction, \(\gamma_i\), in a clumped medium (with volume filling factor \(f\)) is (in cgs units)

\[
\gamma_i = \left(\frac{4\pi \mu m_u v_\infty}{\ln(10) f^{0.25}}\right)^{1.5} \left(\frac{\sqrt{\frac{7}{M}}}{I_u(T)}\right)^{1.5} \frac{1}{F_u(T) \sqrt{\pi A_{ul} h_{ul}}} 2D I_{ul}
\]

where \(D\) is the stellar distance, \(I_{ul}\) is the line flux of the transition with energy \(h_{ul}\) between upper level \(u\) and lower level \(l\), with transition probability \(A_{ul}\). \(\gamma_e = (1.008)\) and \(T_e = (14000)\)K are the electron number density and temperature in the line-forming region, and the mean molecular weight is \(\mu = (4.04)\) for EZ CMa, with \(m_H\) the mass of the hydrogen atom. The integral part, \(F_u(T)\), is

\[
F_u(T) = \int_0^{\infty} \frac{f_u(N_e, T)}{\sqrt{N_e}} d\log(N_e).
\]

where \(f_u\) is the fractional population of the upper level.

Following this technique, we derive Ne^{2+}/He = 1.2×10\(^{-4}\) and O^{3+}/He = 4.2×10\(^{-5}\) by number, assuming a fractional contribution of 67% and 85% to the observed 15.5μm and 25.9μm lines respectively. If we were to neglect the predicted He II contribution to the observed spectral features, we would obtain Ne^{2+}/He = 1.8×10\(^{-4}\) and O^{3+}/He = 4.8×10\(^{-5}\) from this method. Applying the same technique based on the Schmutz (1997) spectroscopic results, we would derive slightly lower abun-
Fig. 2.— Comparison between de-reddened far-UV (HUT), UV (IUE), optical (Torres-Dodgen & Massey 1988), near-IR (ISO) and mid-IR (Spitzer) spectrophotometry of EZ CMa with our synthetic model (dotted), corrected for interstellar atomic hydrogen with log(N(HI))=20.7 cm$^{-2}$ (Howarth & Phillips 1987). Note that the predictions from our non-LTE analysis are included here, such that specifically the fine-structure lines are not synthesised.

Dances of Ne$^{2+}$/He = 1.1–1.4×10$^{-4}$ and O$^{3+}$/He = 3.5–4.1×10$^{-5}$.

Of course, one needs to account for potential contributions from unseen ionization stages. Our model atmosphere identifies the following dominant ions at the outer model radius of ∼200$R_\ast$, where log($n_e$/cm$^3$) ∼ 9, namely He$^+$, C$^{3+}$, N$^{3+}$, O$^{3+}$, Ne$^{2+}$, Mg$^{2+}$, Si$^{4+}$, P$^{4+}$, S$^{4+}$, Cl$^{4+}$, Ar$^{4.5+}$, Ca$^{4+}$, Cr$^{4+}$, Mn$^{5+}$, Fe$^{4.5+}$ and Ni$^{5+}$. The dominant ionization state in WN stars at large radii is predicted to be higher than for WC stars, despite similar
stellar temperatures, since the effects of metal coolants is far less (Hillier 1988, 1989). Are these predictions consistent for the physical conditions at even lower densities of log(n_e/cm^3) \sim 5 where the fine-structure lines form?

The absence of [S iv] 10.5\mu m is consistent with a dominant ionization stage of S^{4+} for EZ CMa, whilst [Ne iii] 12.8\mu m line is absent, so Ne^+ \ll Ne^{2+}, in agreement with expectation. The contribution of Ne^{3+} is uncertain, although it has a rather high ionization potential (IP = 97eV), such that we assume Ne/He \approx Ne^{3+}/He = 1.2–1.8 \times 10^{-4}, depending on the contribution by He ii. This is in reasonable agreement with the revised Solar Ne abundance (Asplund et al. 2004) of Ne/He=2 \times 10^{-4}, adjusted for the H-depleted atmosphere of an early WN star.

For oxygen, we expect that O^{3+} is the dominant ionization stage, but are unable to verify the absence of fine-structure O^{2+} lines, which lie at 51.8 and 88.2\mu m, longward of the IRS passband. Nevertheless, from the consistency with other relevant ions of Ne and S, we adopt O/He \sim O^{3+}/He = 4.2–4.8 \times 10^{-5}. From our nitrogen abundance derived above, we find N/O=40–48 by number. What is the expected oxygen abundance in a H-free WN star? From the spectroscopic analysis above, we derive N/C=40 by number. This may be compared with recent predictions for (initially) rotating massive stars (Meynet & Maeder 2003). At the end of H-burning, the 60–120M_\odot tracks for initial equatorial rotation velocities of 300 km s^{-1} predict N/C=40–45 by number, in perfect agreement. At this stage, N/O=30–50 by number, such that the measured value lies in precisely the predicted range.

4. SUMMARY

We present Spitzer IRS spectroscopy for EZ CMa (HD 50896 WN4b), the first early WN star to be observed spectroscopically in the mid-IR. In addition to numerous stellar wind lines of He ii, fine structure lines of [Ne iii] and [O iv] are revealed, permitting an estimate of the asymptotic wind velocity, \sim 1860 km s^{-1}, plus elemental abundances. We carry our a spectroscopic analysis of HD 50896, allowing for metal line blanketing and wind clumping, revealing generally excellent agreement with the IRS spectroscopy, plus stellar parameters supporting the earlier study of Schmutz (1997), based on an alternative line blanketing technique. We also derive N/He\sim 2 \times 10^{-3} by number, with N/C\sim 40. From the derived clumped mass-loss rate, we obtain Ne^{3+}/He=1.2 \times 10^{-4}, allowing for the contribution by neighboring He ii wind lines, in comparison with Ne/He=2 \times 10^{-4} for a severely H-depleted environment, adjusted for the recent downward revision in the Solar neon abundance by Asplund et al. (2004). An indication of the uncertainty in the fine-structure derived Ne abundance may be obtained by adopting the spectroscopic results for EZ CMa from Schmutz (1997), leading to a 10–20% difference. In addition, we obtain O^{3+}/He=4.2 \times 10^{-5}, i.e. N/O=48, in excellent agreement with evolutionary predictions for massive stars at the end of core H-burning.

We are of course grateful to John Hillier for the use of his non-LTE atmospheric code and to the referee Werner Schmutz for his constructive comments.
