Cholangiocytes and the environment in primary sclerosing cholangitis: where is the link?

Steven P O’Hara,1 Tom H Karlsen,2,3 Nicholas F LaRusso1

In primary sclerosing cholangitis (PSC), annular fibrosis around intrahepatic and extrahepatic bile ducts leads to progressive liver disease for which there is no effective therapy except liver transplantation.1 The concentric accumulation of connective tissue around bile ducts suggests that the cholangiocyte plays an integral role in PSC pathogenesis. However, what initiates changes in cholangiocyte phenotype and how cholangiocytes interact with cells in the peribiliary extracellular matrix like immune cells and stromal components is largely unknown. Over the last 10 years, genome-wide association studies in PSC have revealed >20 risk genes.2–4 A significant observation that can be derived from these data, which also applies to other non-Mendelian phenotypes, is that the predominant risk contribution is likely to come from one or more environmental sources, rather than the genetic aberrations. Indeed, in PSC, we estimate that <10% of the overall liability is accounted for by the genetic findings; with extrapolations into hypothetical, larger study populations, it is unlikely to exceed 30%–40%.6,7 Research dissecting the remaining environmental contribution to PSC and other complex diseases is methodologically challenging. The exposures of an organism throughout life as a whole have recently been referred to as the exposureome8 and include a myriad of components of both the external (eg, xenobiotics) and internal (eg, gut microbes) milieu.

There is a long tradition and effective means for detecting infectious exposures in medicine. Robert Koch in the late 19th century proposed criteria to identify a disease as infectious.9 These included (i) the organism is regularly associated with the disease, (ii) the organism can be isolated from the diseased host and grown in culture and (iii) the disease can be reproduced when the organism is introduced into a healthy susceptible host. With the development of nucleic acid sequence-based identification of microbes, as well as the recognition that the behaviour of a particular microbe can be influenced by the community in which it resides, Koch’s original postulates have evolved.10,11 More specifically, the concept has developed to incorporate culture-independent techniques that can identify putative pathogen nucleic acid sequences or even microbe-derived products (eg, short-chain fatty acids) in association with a diseased tissue that decrease with resolution of disease and increase with clinical relapse.12 These ideas suggest that ‘the scientific community should consider infectious disease causation in a broader systems biology context’ and ‘as technology advances and new scientific discoveries are made, there must be dynamic adaptation of Koch’s postulates…’.10 Recent examples of an expanded paradigm thus incorporate the transfer of body weight-associated, IgA-associated or liver injury-associated gut microbiota in causation of obesity, IBD or alcoholic hepatitis, respectively.12–14

There is less of a tradition and only preliminary tools to detect non-infectious environmental exposures in medicine. In light of the strong environmental component in PSC liability determined by the genetic studies, a reconsideration as to how PSC may fulfil the revised Koch’s criteria is however timely. A rationale for this proposition can be made on several accounts (figure 1). Therein) and the liver in PSC was established 50 years ago with the observation that PSC frequently occurred in the setting of IBD.39–40 A series of studies recently published in Gut have demonstrated that...
Figure 1  Model of cholangiocyte activation. (A) Bile ducts are lined by cholangiocytes, specialised epithelia that under normal physiological conditions modify bile through the transport of water, ions and solutes. Portal myofibroblasts are adjacent to bile duct epithelia within the portal tract and are distinct from hepatic stellate cells which line the hepatic sinusoids; both can differentiate to matrix depositing myofibroblasts under injurious conditions. (B) Cholangiocytes exist in a harsh environment and are exposed to a variety of insults such as microbes, pathogen-associated molecular patterns, danger-associated molecular patterns, xenobiotics and bile acid-induced damage during cholestasis (from a variety of potential mechanisms, eg, oxidative stress). Recognition of these insults, for example, via pathogen recognition receptors or damage-associated molecular pattern receptors, promotes an activated cholangiocyte phenotype characterised by increased proliferation and secretion of profibrotic (eg, connective tissue growth factor) and proinflammatory (eg, interleukin 6 and 8) mediators. In this model, the activated cholangiocyte promotes hepatobiliary repair processes and recruits a variety of innate (eg, macrophages) and professional (eg, T cell) immune cells. On persistent insult, some injured cholangiocytes enter the cellular state of senescence, characterised by withdrawal from the cell cycle, and transition to a hypersecretory proinflammatory state, that is, senescence-associated secretory phenotype. On persistence, such an inflammatory/fibrotic environment will lead to sclerosing cholangitis. Reproduced with permission of Kari C. Toverud.

the gut microbiome in PSC is distinct from those microbial communities observed in IBD patients without PSC and healthy controls.41-44 The relationship between the gut microbial communities and the liver is bidirectional, meaning that there is an impact from host factors onto the gut microbiota by bile and intestinal secretions and the immune system, as much as from microbial metabolites and constituents provided via the gut mucosa and the portal circulation (figure 2).11-17 Support for a role of intestinal microbiota in PSC also comes from studies performed in germ-free mice. In the biliary bile acid toxicity model (Abcb4−/−), an aggravation of bile duct disease was observed in the germ-free animals compared with conventionally raised mice.45 In contrast, in the immune-driven NOD.c3c4 model, an amelioration of bile duct disease was observed in the germ-free animals.46 These differences highlight the complexity of the relationship between gut-derived exposures and the liver and the bile ducts, and suggest that various components of PSC pathogenesis may be affected differently. Further studies are now urgently needed to link the microbial community alterations of PSC and their metabolic and immunological consequences for hepatobiliary physiology and disease.

Given the above considerations supporting the importance of the environment in the pathogenesis of PSC, many key questions remain largely unanswered. For example, what is the nature of a potential environmental exposure in PSC? Is it a small molecule or a peptide-derived substance? Is it diet or microbial in origin (or both, meaning xenobiotic transformed by microbial metabolism)? Is it singular and specific in nature (like gluten in coeliac disease) or is it a compound microbial impact (like most likely the case
The gut–liver relationship in primary sclerosing cholangitis (PSC). There is a bidirectional relationship between the gut and the liver in terms of delivery of a number of endogenous metabolites and bioactive compounds to the gut (e.g., bile acids). Reversely, there is an ongoing delivery of compounds from the intestinal environment via portal blood to the liver. In this bilateral concept, the gut microbiota and the liver comprise an integrated physiological machinery under the influence of endogenous as well as external factors, in which the role of cholangiocytes warrants further attention. in Crohn’s disease? Are there different factors responsible for triggering and driving disease, respectively? At this time, answers to these questions can only be provided based on circumstantial evidence. From the genetic perspective, the strong human leucocyte antigen (HLA) class II associations (DRB1) are suggestive of at least one singular causative compound of key importance, similar to the situation in coeliac disease or drug-induced injury (figure 3). In comparison, the genetic architecture of non-autoimmune, inflammatory diseases like Crohn’s disease is largely different (figure 3), possibly due to a broader spectrum of environmental factors being involved. Further to this thinking, in coeliac disease and drug-induced liver injury, the site of metabolism is crucial for disease localisation (in coeliac disease by transglutaminase 2 in the proximal intestine, in drug-induced liver injury in the liver). In PSC, disease distribution stretches across the distal ileum throughout most of the colon (with a right-sided predominance) into the entire surface of the intrahepatic and extrahepatic bile ducts. Our knowledge of the metabolic machinery of the epithelium in the biliary fraction of this

Figure 2  The gut–liver relationship in primary sclerosing cholangitis (PSC). There is a bidirectional relationship between the gut and the liver in terms of delivery of a number of endogenous metabolites and bioactive compounds to the gut (e.g., bile acids). Reversely, there is an ongoing delivery of compounds from the intestinal environment via portal blood to the liver. In this bilateral concept, the gut microbiota and the liver comprise an integrated physiological machinery under the influence of endogenous as well as external factors, in which the role of cholangiocytes warrants further attention. Figure 3  Genome-wide association study outcomes shown as Manhattan plots. In primary sclerosing cholangitis (PSC) and prototypical autoimmune diseases, there is a strong human leucocyte antigen association (chromosome 6). A similar genetic architecture is also seen in diseases elicited by specific environmental exposures (exemplified by drug-induced liver injury and coeliac disease). This contrasts the situation in diseases where a compound environmental insult is involved, exemplified by Crohn’s disease. The figure shows Manhattan plots with results of genome-wide association studies in (A) PSC, (B) flucloxacillin-induced liver injury, (C) coeliac disease and (D) Crohn’s disease. The X axis shows the chromosomal location, the Y axis the \(-\log_{10} p\) values of the association statistics. Panel (B) is reproduced with permission from Ref. 19. Panels (A), (C) and (D) plotted from data in Ref. 20.
In summary, the evolution of Koch’s postulates based on the availability of new technologies, the similarities in the intra-cellular signalling pathways, processes and pathophysiological outcomes of SSC versus PSC, as well as recent data strongly implicating an important role for the intestinal microbiome in PSC, all justify serious consideration and further experiments to test the possibility that PSC is caused by an environmental exposure. Genetic and environmental factors are inseparable and co-dependent in the causation of PSC as in any disease, and specific genetic findings made over the last decade, HLA related in particular, may for this reason guide the way forward in a methodologically challenging research space. The molecular machinery of the cholangiocyte is likely to play a key role at this gene–environment intersection, and basic research to enhance our understanding of normal and activated cholangiocyte function is urgently needed to test for their involvement with putative pathogenic factors.

Figure 4 A coeliac disease model of primary sclerosing cholangitis (PSC) susceptibility. In coeliac disease, the disease-associated human leucocyte antigen (HLA) variants direct the adaptive immune response to gluten. Exposure to gluten, as well as the resulting gluten-specific adaptive immunity, respectively, is required to maintain autoantibody production and immunopathology in coeliac disease. Such observations challenge the concept that autoimmunity requires immune activation towards self-antigens. It may thus be hypothesized that the strong genetic HLA associations in PSC (and other autoimmune diseases) point to specific causal environmental exposures determined by the HLA/antigen (Ag)/T-cell receptor (TCR) interactions. Within this concept, genetic and environmental factors are co-dependent in disease causation with the implication that genetic risk factors may hold clues as to the identity of pathogenic environmental factors.
