**Abstract**

*Shigella sonnei* is responsible for the majority of shigellosis infections in the US with over 500,000 cases reported annually. Here, we present the complete genome of the clinical multidrug resistant (MDR) strain 866, which is highly susceptible to bacteriophage infections. The strain has a circular chromosome of 4.85 Mb and carries a 113 kb MDR plasmid. This IncB/O/K/Z-type plasmid, termed p866, confers resistance to five different classes of antibiotics including ß-lactamase, sulfonamide, tetracycline, aminoglycoside, and trimethoprim. Comparative analysis of the plasmid architecture and gene inventory revealed that p866 shares its plasmid backbone with previously described IncB/O/K/Z-type *Shigella* spp. and *Escherichia coli* plasmids, but is differentiated by the insertion of antibiotic resistance cassettes, which we found associated with mobile genetic elements such as Tn3, Tn7, and Tn10. A whole genome-derived phylogenetic reconstruction showed the evolutionary relationships of *S. sonnei* strain 866 and the four established *Shigella* species, highlighting the clonal nature of *S. sonnei*.

**Key words:** *Shigella sonnei* strain 866, multidrug resistance (MDR), whole genome sequencing, comparative phylogenomics.

**Introduction**

*Shigella sonnei*, together with *Shigella flexneri*, is responsible for more than 90% of shigellosis cases in the US (Scallan et al. 2011), causing an estimated 500,000 infections, 6,000 hospitalizations and 70 deaths annually (Mead et al. 1999; Gupta et al. 2004). Historically, *S. sonnei* has been responsible for bacillary dysentery in developed countries but its recent emergence and spread into developing countries over the last decades has raised major public health concerns (Vinh et al. 2009). Unlike other *Shigella* spp., *S. sonnei* is genetically homogenous (Karaolis et al. 1994) and descended from a clonal, rapid-evolving multidrug resistant (MDR) ancestor that diversified into distinct lineages (Holt et al. 2012). MDR strains that confer resistance to different classes of antibiotics have been described (Jain et al. 2005; Kozyreva et al. 2016).

An important virulence factor in *Shigella* spp. is the Shiga toxin, first discovered in the 19th century in a *Shigella dysenteriae* clinical isolate by Kiyoshi Shiga (Trofa et al. 1999), which is also a hallmark of Shiga toxin-producing *Escherichia coli* (STEC) (Eppinger et al. 2011; Sadiq et al. 2014). Although not all *Shigella* spp. or *S. sonnei* isolates are shigatoxigenic, Stx can be laterally acquired through Stx phage infection, either from (STEC) or Stx-producing *Shigella* strains (Strauch et al. 2001; Nyholm et al. 2015). Other key virulence determinants of *Shigella* are long polar fimbriae (*ipfA*), P-related fimbria regulatory gene (*prfB*), *Shigella* Iga-like protease homolog (*sIGA*), plasmid-encoded enterotoxin (*senB*), glutamate decarboxylase (*gad*), invasion protein *S. flexneri* (*ipDA*), or VirF transcriptional activator (*virF*), among others as reviewed in Mattock and Blocker (2017).
Strain 866 has been found to be highly susceptible to infection by a range of phages, including Cytotolethal Distending Toxin and Stx-converting prophages found in STEC, as previously demonstrated (Muniesa 2004; Allué-Guardia et al. 2011; Imamovic and Muniesa 2011). This observation highlights the potential epidemiological role of this particular strain in the acquisition and spread of phage-borne pathogenicity factors into larger host-pathogen populations by means of bacteriophage transduction. The availability of the closed high-quality 866 genome presented in this study is foundational to further elucidate genome characteristics correlated with its virulence, resistance, and bacteriophage susceptibility.

Materials and Methods

*Shigella sonnei* 866

The clinical *S. sonnei* strain 866 was isolated from human feces in September of 2000 in Hospital de la Santa Creu i Sant Pau in Barcelona, Spain. Species identification was confirmed by an array of biochemical tests (API 20E, Sant Pau in Barcelona, Spain). Species identification was confirmed by an array of biochemical tests (API 20E, BioMérieux, Marcy-l’Étoile, France) (supplementary table 1), following the manufacturer’s instructions. As demonstrated previously, strain 866 is highly susceptible to lysogenic phage infection and prophage genome incorporation (Muniesa 2004; Allué-Guardia et al. 2011; Imamovic and Muniesa 2011).

**Genome Sequencing, Assembly, and Annotation**

The strain was cultured in Luria-Bertani broth (Fisher Scientific, Thermo Fisher Scientific, Asheville, NC, USA) overnight at 37°C in a shaker (180 rpm). Total genomic DNA was extracted from the overnight culture using the QIAamp DNA Mini Kit (Qiagen, Inc., Valencia, CA, USA) according to the manufacturer’s protocol. To close the genome, we pursued a hybrid approach using long-read PacBio RS II and short-read Illumina MiSeq sequencing. Briefly, for PacBio sequencing, genomic DNA was sheared into 20-kb fragments using g-TUBE (Covaris, Inc., Woburn, MA, USA). The library was prepared based on the 20-kb PacBio sample preparation protocol and sequenced using P6/C4 chemistry on four single-molecule real-time (SMRT) cells with a 240-min collection time. The continuous long-read data were de novo assembled using the PacBio hierarchical genome assembly process (HGAP version 3.0) (Chin et al. 2013) with default parameters in SMRT Analysis v2.3.0, including consensus polishing with Quiver (Chin et al. 2013). For Illumina sequencing, a paired-end library was prepared using the NxSeq AmpFREE Low DNA Library Kit (Lucigen) and sequenced with 250-bp read length using the MiSeq Reagent kit v2 500-cycle (Illumina) following the manufacturer’s guidelines. Illumina reads were utilized for PacBio sequence error correction using Pilon (Walker et al. 2014). The chromosomal and plasmid origin of replication, oriC (http://ubic.tju.edu.cn/Ori-Finder/; last accessed August 06, 2018) (Gao and Zhang 2008) and repA, respectively, were determined and designated as the zero point of the closed molecules prior to annotation using the NCBI Prokaryotic Genome Annotation Pipeline (PGAP) (Tatusova et al. 2016).

**Comparative Phylogenomics**

After assembly and annotation, virulence and antibiotic resistance (AR) genes in the 866 chromosome and plasmid were detected *in silico* by VirulenceFinder (https://cge.cbs.dtu.dk/services/VirulenceFinder/; last accessed August 06, 2018) (Joensen et al. 2014) and ResFinder (https://cge.cbs.dtu.dk/services/ResFinder/; last accessed August 06, 2018) (Zankari et al. 2012), respectively. Prophages and plasmid incompatibility groups were identified using PHASTER (Zhou et al. 2011; Arndt 2016) and PlasmidFinder (http://cge.cbs.dtu.dk/services/PlasmidFinder/; last accessed August 06, 2018) (Carattoli et al. 2014), respectively. BLASTn (Altschul et al. 1990) of the complete p866 sequence against the NCBI non-redundant database identified a number of *Shigella* and *E. coli* IncB/OK/Z-type plasmids as closest phylogenetic relatives. Respective plasmid gene inventories were compared with BLAST atlas in the GView server (https://server.gview.ca; last accessed August 06, 2018) (Petkau et al. 2010). To further establish the phylogenetic relatedness of strain 866 within *Shigella*, we selected a total of 26 representative *S. sonnei*, *S. flexneri*, *S. dysenteriae*, and *S. boydii* genomes from NCBI (supplementary table 2) to capture the plasticity within the four established *Shigella* species (Sahl et al. 2015). The phylogeny was inferred from the whole genome alignment using Mussy (Angiuoli and Salzberg 2011) and RAxML (Stamatakis 2014) with 100 bootstrap replicates. The tree was visualized in Geneious (Kearse et al. 2012) and decorated with strain-associated metadata in Evolview (Zhang et al. 2012; He et al. 2016).

**Results and Discussion**

Pathogenome Architecture and Inventory

A hybrid strategy using long-read PacBio and short-read Illumina technologies allowed us to sequence the *S. sonnei* strain 866 genome to closure with high chromosomal and plasmid coverage of 107x and 134x. The genome is comprised of a 4,849,628 bp chromosome and a 113,079 bp MDR plasmid, termed p866, with an average GC content of 51% for both molecules. Strain 866 lacks the large virulence plasmid pSS, which encodes the wbg Phase I O antigen cluster, and thus features a rough colony morphology (Kopecko et al. 1980; Caboni et al. 2015).

After assembly and annotation, virulence and antibiotic resistance (AR) genes in the 866 chromosome and plasmid were detected *in silico* by VirulenceFinder (https://cge.cbs.dtu.dk/services/VirulenceFinder/; last accessed August 06, 2018) (Joensen et al. 2014) and ResFinder (https://cge.cbs.dtu.dk/services/ResFinder/; last accessed August 06, 2018) (Zankari et al. 2012), respectively. Annotation with PGAP (Tatusova et al. 2016) predicted a total of 4,482 coding sequences (CDS), 96 tRNAs, and 22 rRNAs. The annotated chromosome and plasmid p866 have
been deposited in GenBank under accession numbers CP022672 and CP022673, respectively.

Whole Genome Phylogenetic Analysis

To determine the evolutionary relationship of S. sonnei strain 866 within Shigella, we established a phylogenetic framework by including representative S. sonnei, S. flexneri, S. boydii, and S. dysenteriae genomes (supplementary table 2) to capture diversity among the four species (fig. 1). The resulting whole genome-based phylogeny positions strain 866 into clade S2, a group exclusively comprised of S. sonnei isolates, indicative of the clonal nature of S. sonnei (Karaolis et al. 1994). The genetic homogeneity of this cluster was further confirmed by whole genome comparison, as evidenced by the high degree of the overall nucleotide sequence similarity in the genomes (supplementary fig. 1). The tree topology partitions the isolates into five distinct clusters (S1–S5). Unlike the monophyletic S. sonnei clade S2, the phylogenetic clustering does not corroborate with the Shigella species designation.

Virulence and Resistance Profile of S. sonnei 866

The Shigella genome is highly dynamic, and mobile elements are major drivers of the S. sonnei pathogenome evolution (Jiang et al. 2005; Chang et al. 2011; Juhas 2015). Phage profiling by PHASTER (Arndt 2016) showed that strain 866 carries a highly diverse inventory of 17 prophages, including seven complete and several predicted prophage remnants. Details of respective prophage chromosomal position, length, GC content, and number of predicted CDS are provided in supplementary table 3. Identified prophage regions show partial homologies to several enterobacteria phages, such as, for example, phiP27, P1, Gifsy-2, lambda, or SEN34 (Parajuli et al. 2017). These phage-borne loci encode important virulence determinants, such as the invasion plasmid antigen IpaH9.8, an E3 ubiquitin ligase that interferes with the host’s ubiquitination pathways and facilitates colonization (Okuda et al. 2005). We also noted that the majority of the 866 prophages carry transposons and IS elements that are known drivers of mobile virulence and resistance factors that can be acquired or lost through independent evolutionary events (Ke et al. 2011; Holt et al. 2012; Sadiq et al. 2014; Parajuli et al. 2017).
bacteriophage diversification (Eppinger et al. 2011; Yin et al. 2015). Bacteria often carry an array of prophages in their genomes. The benefits conferred by polylysogeny are poorly understood, but previous reports show that in mixed infections with phage-free bacteria, phage carriage, and especially multiple phage carriage, is highly beneficial and provides a fitness advantage during mixed infections by mediating bacteria–bacteria competition (Burns et al. 2015). Moreover, many bacteria use their prophages as weapons against competitors. Because the different temperate phages are likely to have different host ranges, this expands the range of bacterial competitors that the polylysogen can kill (James et al. 2012).

This strain features virulence hallmarks of _S. sonnei_ such as _lpfA, ipaH9.8, gad, senB_, and _sigA_ (Okuda et al. 2005; Al-Hasani et al. 2009; Torres et al. 2009; Joensen et al. 2014; Mattock and Blocker 2017). We further identified an arsenal...
of five AR loci on the MDR-plasmid p866 (fig. 2A), which renders this strain β-lactamase (blaTEM-1A), sulfonamide (sul2), tetracycline (tetB), aminoglycoside (aadA1), and trimethoprim (dfrA) resistant (Zankari et al. 2012; Miranda et al. 2016).

Phylogenetic Relatedness and Gene Inventory of MDR-Plasmid p866

To elucidate phylogenetic relatedness of the MDR plasmid, we performed a nucleotide BLASTn (Altschul et al. 1990) search of the complete p866 plasmid sequence against the non-redundant database at NCBI. We, hereby, identified several plasmids of diverse E. coli and Shigella pathovars that share high similarity at the nucleotide level (>99%) with a coverage of the plasmid backbones ranging from 72% to 79%. Namely, E. coli plasmids pHUSEC41-1, from an EAEC O104: H4 hybrid strain from the 2011 outbreak in Germany (Kunne et al. 2012), pEC31 (KU932021.1), pR3521 (Papagiannitsis et al. 2011), and pHUSEC411, from ExPEC O18: K1 strain PMV-1 (Peris-Bondia et al. 2013). Further, S. dysenteriae 1 plasmids p69-3818 (strain 69-3818, Guatemala 1969) and p92-9000 (strain 92-9000, Panama 1991) (Njampkeo et al. 2016). Here, we note that the phylogenetic closest S. sonnei plasmids in the NCBI repository show only ~68% sequence coverage, as seen for plasmids pSH15sh99 (KY471628.1) or pSH15sh104 (KY471629.1).

We compared both the p866 coding capacity and plasmid architecture among these phylogenetically related plasmids, which are all of the IncB/O/K/Z incompatibility group (Kozyreva et al. 2016). Nucleotide-level analysis using BLAST atlas (Petkau et al. 2010) shows a largely syntenic shared plasmid backbone of ~86 kb that is highly conserved (fig. 2A). It encodes operons for type IV pilus biogenesis, conjugal transfer, and plasmid maintenance, which altogether account for more than 50% of the shared plasmid backbone. Our analysis clearly shows that microevolution in this MDR plasmid is driven by transposon (Tn) insertions into the plasmid backbone. As shown in figure 2A, four of the five AR loci were introduced by insertion of three transposable elements that disrupt plasmid synteny: Tn3 (blaTEM-1A), Tn7 (aadA1 and dfrA), and Tn10 (tetB) (Bailey et al. 2011; Nogrady et al. 2013; Kozyreva et al. 2016), although the sul2 gene is part of the E. coli and S. sonnei p866 plasmid backbone. The prototypical Tn7 is plastic in its carried resistance gene cassettes and encodes seven genes (tnsABCDE) required for transposition (Peters and Craig 2001). In case of p866 Tn7, we found that Tn7 (tnsCD) loci are missing, likely due to a secondary insertion of Tn10 in-between the Tn7 (tnsEF) (fig. 2B). Transposon Tn3 appears intact while Tn10 lacks the left IS10 repeat, which might impair its mobility (Chalmers et al. 2000; Lawley et al. 2000; Haniford and Ellis 2015). Details of the respective Tn sequence compositions including inverted repeats can be found in figure 2B and C.

Comparison of AR profiles among these plasmids shows that trimethoprim (dfrA) resistance is uniquely found in p866 as an integral component of Tn7 (fig. 2A). Both p866 and the two S. dysenteriae plasmids confer aadA1 and tetB resistance, though the respective streptomycin loci are found in different transposon contexts; Tn7aada1 in p866 and Tn21aada1 (Liebert et al. 1999), in case of S. dysenteriae (fig. 2B). Strain 866 carries another transposon-encoded resistance on Tn3blaTEM-1A (fig. 2C), a feature shared by all compared E. coli plasmids with the exception of pHUSEC411. In contrast, sulfonamide (fig. 2B) was identified as an integral part of the E. coli plasmid backbone. The observed prevalence and mosaic structure of the transposon resistance cassettes stresses their role as major drivers of IncB/O/K/Z-type plasmid evolution. Plasmid spread into broader host populations crossing E. coli and Shigella pathovar boundaries is likely facilitated by the conjugal transfer system found on its backbone (fig. 2A).

The emergence of MDR bacteria has been identified by the World Health Organization as a pressing global public health problem. An emerging threat is posed by the spread of antibiotic resistant S. sonnei isolates (Puzari et al. 2017), the major culprit of human shigellosis within last decades (Sivapalasingam et al. 2006; Kahsay and Muthupandian 2016; Taneja and Mewara 2016), which has an exceptional ability to laterally acquire and transfer resistance genes (Ke et al. 2011; Holt et al. 2012; Thompson et al. 2015; Sváň et al. 2017; Rajpara et al. 2018). Using whole genome sequencing and typing strategies, we have elucidated the genomic make-up and phylogenetic relationship of the clinical S. sonnei strain 866 and identified the genomic basis of AR against five classes of antibiotics on the carried MDR-plasmid p866. The microevolution of this IncB/O/K/Z-type plasmid is driven by different Tn insertions that render strain 866 MDR. The carried conjugal transfer backbone of p866 makes it an ideal vehicle for the lateral spread of resistance loci into diverse E. coli and Shigella pathovars (fig. 2A) and potentially other enterics of clinical importance. Monitoring emerging trends in the S. sonnei pathogenome evolution is thus critical to translate sequence-based information into actionable countermeasures to detect and prevent the spread of MDR resistant Shigella clones. Identified genome signatures of such emerging highly virulent and AR resistant clones are readily applicable for improved biosurveillance, risk assessment, and informed and improved therapeutic strategies (Qany et al. 2017; Pinaud et al. 2017).
