Abstract
The Dirac equation describes the dynamics of a relativistic spin-1/2 particle regarding its spatial motion and intrinsic degrees of freedom. Here we adopt the point of view that the spinors describe the state of a massive particle carrying two qubits of information: helicity and intrinsic parity. We show that the density matrix for a gas of free fermions, in thermal equilibrium, correlates helicity and intrinsic parity. Our results introduce the basic elements for discussing the spin-parity correlation for a Fermi gas: (1) at the ultra-relativistic domains, when the temperature is quite high, $T > 10^{10} K$, the fermions have no definite intrinsic parity (50% : 50%), which is maximally correlated with the helicity; (2) at very low temperature, $T \approx 3 K$, a unique parity dominates (conventionally chosen positive), by $10^{20}$ to 1, while the helicity goes into a mixed state for spin up and down, and the quantum correlation decoheres. For the antifermions we get the opposite behavior. In the framework of quantum information, our result could be considered as a plausible explanation of why we accept, as a fact (consistent with the experimental observation), that fermions (and antifermions), in our present epoch of a cool universe, have a unique intrinsic parity. The framework for constructing spin-parity entangled states is established.

Keywords: dirac equation, entanglement, mutual information, fermi gas

(Some figures may appear in colour only in the online journal)

1. Introduction

Dirac invented his equation in order to explain the quantum properties of the electron (spin $1/2$) in the relativistic framework: the equation had to (a) display the formula $E = \sqrt{\vec{p}^2 + m^2}$ as the eigenenergy of a particle in free motion (with $\hbar = c = 1$); (b) be covariant under a Lorentz transformation that links the particle dynamical properties between two inertial frames. Dirac found that the sound equation had to be expressed, necessarily, in terms of $4 \times 4$ matrices. Its more familiar form is $i\partial \psi (\vec{x}, t) / \partial t = \mathbf{H}_0 \psi (\vec{x}, t)$, with the Hamiltonian being linear in the momentum $\vec{p}$,

\[ \mathbf{H}_0 = \vec{a} \cdot \vec{p} + m \beta, \]

and the $4 \times 4$ matrices $\vec{a} \equiv (a_+, a_-, a_y)$ and $\beta$, have to satisfy forcefully the relations

\[ a_+ a_+ + a_- a_- = 2 \mathbf{I}, \quad a_+ \beta + \beta a_- = 0, \quad \beta^2 = \mathbf{I}. \]

with $\mathbf{I}$ for the unit matrix (in Dirac’s book [1], instead of $\vec{a}$ we find a $4 \times 4$ matrix $\rho_1$ multiplying the $4 \times 4$ direct product of Pauli matrices $\vec{\sigma} \equiv (\sigma, \sigma, \sigma)$). An usual approach consists in the introduction of the chiral representation, where the components of the matrix vector, $( \mathbf{I}, \vec{\sigma}) = \sigma$ and $( \mathbf{I}, - \vec{\sigma}) = \vec{\sigma}$, are respectively in contravariant and covariant forms, in the same fashion that one has $(\psi, \phi) = (t, x)$ and $(\psi, \phi) = (t, -x)$ [2]. The state vector solution to the Dirac equation can be written as the sum,

\[ \psi (x) = \begin{pmatrix} \psi_+ (x) \\ 0 \end{pmatrix} + \begin{pmatrix} 0 \\ \psi_- (x) \end{pmatrix}, \]

0031-8949/14/075105+07$\$33.00 © 2014 The Royal Swedish Academy of Sciences Printed in the UK
of left and right chiral spinors
\[ \psi_L(x) = \begin{pmatrix} \varphi_{L1}(x) \\ \varphi_{L2}(x) \end{pmatrix}, \quad \psi_R(t) = \begin{pmatrix} \chi_{L1}(x) \\ \chi_{L2}(x) \end{pmatrix}, \]
and \( x \equiv (\vec{x}, t), \quad \theta \equiv \begin{pmatrix} 0 \\ 0 \end{pmatrix}. \) From the Dirac equation plus equations (1) and (3) one constructs two coupled differential equations for the spinors \( \psi_L(x) \) and \( \psi_R(x), \)
\[ i\sigma^\alpha \partial_x \psi_L(x) - m \psi_L(x) = 0, \]
\[ i\sigma^\alpha \partial_x \psi_R(x) - m \psi_R(x) = 0, \]
whose Lagrangian is [2] (omitting the explicit dependence on \( x),
\[ \mathcal{L} = \bar{\psi} \sigma^\alpha \partial_x \psi + i\bar{\psi} \sigma^\alpha \partial_t \psi - m (\bar{\psi} \psi + \psi \bar{\psi}) \tag{4} \]
Interestingly, the Dirac equation allows a different insight when written in terms of direct (or Kronecker) products of Pauli matrices. So, daring to interpret quantum mechanics as a special kind of information theory for particles and fields [3] 1, in the language of quantum information we may say that the relativistic equation of a spin-1/2 fermion has as solution a state of two qubits (two degrees of freedom) carried by a massive particle whose dynamical evolution in space is represented by a continuous variable that may be the position or the linear momentum [4, 5]. Hereon we will choose the linear momentum representation (as a c-number) instead of the spatial parity
\[ \Psi(x) = \begin{pmatrix} \phi_1(x) \\ \psi_1(x) \end{pmatrix}, \quad \Psi(x) = \begin{pmatrix} \phi_2(x) \\ \psi_2(x) \end{pmatrix}, \]
where the upperscripts 1 and 2 refer to qubits 1 and 2, respectively. Thus we write the Dirac Hamiltonian (1) in terms of tensor products of Pauli matrices
\[ \hat{a} = \sigma^i_1 \otimes \sigma^2, \quad \hat{b} = \sigma^i_1 \otimes \mathbf{1}_2, \]
\[ \hat{b} \cdot \vec{p} = \sigma^i_1 \otimes \vec{p}, \]
and \( \hat{b} = \sigma^i_1 \otimes \mathbf{1}_2, \)
\[ \text{where the upperscripts 1 and 2 refer to qubits 1 and 2, respectively. Thus we write the Dirac Hamiltonian (1) in terms of the direct product of two-qubit operators, } \]
\[ \hat{H}_0 = \sigma^i_1 \otimes \vec{p} \vec{2} + m \sigma^i_1 \otimes \mathbf{1}_2, \]
and the two solutions to the Dirac equation are
\[ \begin{pmatrix} \psi^r(\vec{p}, t) \\ \psi^l(\vec{p}, t) \end{pmatrix} = e^{i(1/\hbar \gamma_5) E_\hbar t} \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} \begin{pmatrix} \mathcal{N}(p) \\ \mathcal{N}(p) \end{pmatrix}, \]
\[ \begin{pmatrix} + \mathbf{1}_2 \\ - \mathbf{1}_2 \end{pmatrix} \begin{pmatrix} \psi^r(\vec{p}, t) \\ \psi^l(\vec{p}, t) \end{pmatrix} = \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} \begin{pmatrix} \mathcal{N}(p) \\ \mathcal{N}(p) \end{pmatrix}, \]
(6)
where \( s=0 \) and 1 stand respectively for negative and positive energy solutions, \( \vec{p} = p \hat{p}, \) with \( |\vec{p}| = 1. \) The state \( \begin{pmatrix} \psi(\vec{p}) \end{pmatrix}_\mathcal{Z} \)
is a spinor representing the spatial motion of the free fermion
\[ \begin{pmatrix} \psi(\vec{p}) \end{pmatrix}_\mathcal{Z} \]
in the momentum representation) coupled to its spin, which describes a structureless magnetic dipole moment. For qubit 1 the kets, \( |+\rangle_1 \) and \( |-\rangle_1 \), are identified as the intrinsic parity eigenstates of the fermion. The states are orthogonal, \( \langle \pm \pm (\mp) \rangle = 0 \). For the inner product we get
\[ \begin{pmatrix} \psi^r(\vec{p}, t) \\ \psi^l(\vec{p}, t) \end{pmatrix} = \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} \begin{pmatrix} \mathcal{N}(p) \\ \mathcal{N}(p) \end{pmatrix}, \]
and we also assume that the local probability distribution for the momenta is normalized,
\[ \int d^3p \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} = 1. \]
Thus the spinors and 4x4 matrices stand for the the direct product of the intrinsic degrees of freedom of a massive spin-1/2 fermion, parametrized by the linear momentum \( \vec{p}, \) on free motion in space. Since \( \mathbf{H}_0 \)
\[ \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} = \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix}, \]
one has \( \begin{pmatrix} \mathbf{H}_0 \end{pmatrix} \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} = \begin{pmatrix} \psi^r(\vec{p}) \\ \psi^l(\vec{p}) \end{pmatrix} \) that leads to Einstein’s dispersion relation \( \vec{p}^2 + m^2 = E_\hbar^2 \). As so, the state (6) has no definite intrinsic parity, qubit 1 is in a superposition of both eigenstates.

The total parity operator \( \hat{P} \) acts on the Kronecker product
\[ \begin{pmatrix} \pm \mathbf{1}_2 \otimes \begin{pmatrix} u(\vec{p}) \end{pmatrix}_\mathcal{Z} \end{pmatrix}, \]
\[ \hat{P} \begin{pmatrix} \pm \mathbf{1}_2 \otimes \begin{pmatrix} u(\vec{p}) \end{pmatrix}_\mathcal{Z} \end{pmatrix} = \pm \begin{pmatrix} \pm \mathbf{1}_2 \otimes \begin{pmatrix} u(-\vec{p}) \end{pmatrix}_\mathcal{Z} \end{pmatrix}; \]
indeed it is the product of two operators, the intrinsic parity \( \hat{P}^\alpha \) (having two eigenvalues, \( \hat{P}^\alpha \pm \pm = \pm |\pm \rangle \)) and the spatial parity \( \hat{P}_\text{sp} \)
\[ \hat{P}^\alpha \hat{P}_\text{sp} \equiv \hat{P}_\text{sp} \hat{P}^\alpha, \]
and it follows that \( \hat{P}^\alpha = \hat{P}_\text{sp} \). Regarding the spatial parity operator
\[ \hat{P}_\text{sp} \equiv \begin{pmatrix} \mathcal{P} \end{pmatrix} \begin{pmatrix} \mathcal{P} \end{pmatrix} = \begin{pmatrix} \mathcal{P} \end{pmatrix} \begin{pmatrix} \mathcal{P} \end{pmatrix} + \begin{pmatrix} \mathcal{P} \end{pmatrix} \begin{pmatrix} \mathcal{P} \end{pmatrix}, \]
(6)
the + (−) sign stands for axial (polar) vectors. Complementarily, the \( \gamma \)-matrices are \( \gamma^0 = \mathbf{1}, \gamma^i = \sigma^i \otimes \mathbf{1}, i = 1, 2, 3 \), and \( \gamma^5 = i\sigma_1 \otimes \mathbf{1}, \gamma^5 = i\sigma_1 \otimes \mathbf{1}, \gamma^5 = i\sigma_1 \otimes \mathbf{1}. \)
\[ \text{2. Correlation between the intrinsic degrees of freedom} \]

There is an asymmetry between the two terms within the brackets in the solution (6): the first one represents the limit for the non-relativistic state of a spin 1/2 free fermion, namely, the solution to the Schrödinger equation, while the second term is responsible for the relativistic effect.
Dirac equation solution will make use of the spinors that are normalized with $\chi, \pi$ where a mixing angle, $(we omit the subscript 2) where $\phi$ and $\chi$ determine the direction of $\hat{\rho}$ (on a spherical surface of radius 1 the tips of the versors $\hat{\rho}$ and $-\hat{\rho}$ are localized by the angles $\Omega \equiv (\theta, \phi)$ and $\Omega_\pi \equiv (\pi - \theta, \phi + \pi)$ and the kets $|\uparrow\rangle, |\downarrow\rangle$ stand for $\cos \theta, \sin \theta$. So, the spinor $|\mu (\bar{\rho})\rangle_2$ can be written as the superposition

$$|u (\bar{\rho})\rangle = A (\bar{\rho}) \Omega_\pi + B (\bar{\rho}) |\Omega_\sigma\rangle,$$

where $A (\bar{\rho})$ and $B (\bar{\rho})$ are the density distribution of the linear momentum. The spinor (8) correlates the linear momentum (a c-number) to the helicity eigenstates, however, for simplicity, we are going to assume that the linear momentum is not correlated to the helicity, therefore

$$A (\bar{\rho}) = \varphi (\bar{\rho}) \cos (\chi), \quad B (\bar{\rho}) = \varphi (\bar{\rho}) e^{i \mu} \sin (\chi),$$

where a mixing angle, $\chi \in [0, \pi]$, and a relative phase, $\mu \in [0, 2\pi]$, have been introduced. The helicity sector of the Dirac equation solution will make use of the spinors

$$|u_+ (\bar{\rho})\rangle = \varphi (\bar{\rho}) |\hbar_+\rangle, \quad |u_- (\bar{\rho})\rangle = \varphi (\bar{\rho}) |\hbar_-\rangle, \quad |\hbar_+\rangle = \cos (\chi) |\Omega_\pi\rangle + e^{i \mu} \sin (\chi) |\Omega_\sigma\rangle,$$

$$|\hbar_-\rangle = \hat{\rho} \cdot \hat{\sigma} |\hbar_+\rangle = \cos (\chi) |\Omega_\pi\rangle - e^{i \mu} \sin (\chi) |\Omega_\sigma\rangle$$

that are normalized $\langle \hbar_+ | \hbar_- \rangle = 1$, however they are orthogonal only for $\chi = \pi/4$, because $\langle \hbar_+ | \hbar_- \rangle = \cos (2\chi)$. It is worth noting that doing the changes $\chi \to \pi - \chi$ and $\phi \to \phi + \pi$ we get $|\hbar_+\rangle \to - |\hbar_-\rangle$. For a normalized linear momentum distribution, $\int d^3 p \left| \varphi (\bar{\rho}) \right|^2 = 1$, one has

$$\int d^3 p \left( u_+ (\bar{\rho}) \right) |u_+ (\bar{\rho})\rangle = 1,$$

and

$$\int d^3 p \left( u_- (\bar{\rho}) \right) |u_- (\bar{\rho})\rangle = \cos (2\chi).$$

The simplified form of the time-independent component of state (6) becomes

$$\left| \psi (\bar{\rho}) \right\rangle = \varphi (\bar{\rho}) |\eta (p)\rangle,$$

where

$$\left| \eta (p)\rangle = N (p) \left( |+\rangle \otimes |h_+\rangle_2 \right. \right.$$

$$\left. + \frac{p}{E_p + (-1)^{m+1}} |-_\rangle \otimes |h_-\rangle_2 \right).$$

Calculating the trace over the qubits the result is

$$\text{Tr}_2 \left[ \rho (\bar{\rho}) \right] = \left| \varphi (\bar{\rho}) \right|^2,$$

thus $\int d^3 p \text{Tr}_2 \left[ \rho (\bar{\rho}) \right] = 1.$

For an ensemble of free fermions interacting with a thermal environment at temperature $T$, we identify the probability density $\left| \varphi (\bar{\rho}) \right|^2$ with a normalized distribution function isotropic in the linear momentum, $\int d^3 p \rho (p, T) = 1$. Integrating equation (16) over the linear momentum, the reduced density matrix becomes

$$\rho (\bar{\rho}) = \int_0^\infty dp \int d^3 p \rho (p, T) \left( \int d\Omega \left| \eta (p)\rangle \right\rangle |\eta (p)\rangle \right),$$

where $\int d^3 p \int d\Omega \left| \eta (p)\rangle \right\rangle |\eta (p)\rangle \right.$

$$\int d\Omega \left| \eta (p)\rangle \right\rangle |\eta (p)\rangle = \frac{1}{2} \left( \int d\Omega \right),$$

$$\int d\Omega \left| \Omega_\pi\rangle \right\rangle |\Omega_\sigma\rangle = \frac{\pi}{8} \sigma \left( \int d\Omega \right).$$

where $\mathbf{I} = |+\rangle \langle +| + |1\rangle \langle 1|$ and $\sigma = |+\rangle \langle +| - |1\rangle \langle 1|$ from which, by equation (11), one obtains

$$\left( \int d\Omega \right)^{-1} \int d\Omega \left| \hbar_z\rangle \right\rangle |\hbar_z\rangle = n_z \left( |+\rangle \langle +| + n_z |1\rangle \langle 1| \right),$$

with real coefficients

$$n_z = \frac{1}{2} \pm \pi \sin (2\chi) \cos (\mu).$$
and
\[
\left( \int d\Omega \right)^{-1} \int d\Omega \ |a \rangle \langle b| = \hat{n}_a |1\rangle \langle 1| + \hat{n}_b |1\rangle \langle 1|,
\]
with complex coefficients
\[
\hat{n}_a = \frac{1}{2} \cos (2\phi) \pm \frac{i\pi}{8} \sin (2\phi) \sin (\mu),
\]
noting that \(n_a + n_\bar{a} = 1, \hat{n}_a + \hat{n}_\bar{a} = \cos (2\phi)\) and \(\hat{n}_\bar{a}^\dagger = \hat{n}_a\).

The reduced density operator (17) becomes
\[
\hat{\rho}_{12}^{\dagger} = M_{++}'(T) \left[ |+\rangle \langle +| \otimes (n_+ |1\rangle \langle 1| + n_- |1\rangle \langle 1|) \right]
+ M_{+-}'(T) \left[ |-\rangle \langle -| \otimes (n_- |1\rangle \langle 1| + n_+ |1\rangle \langle 1|) \right]
+ M_{-+}'(T) \left[ |+\rangle \langle +| \otimes (\hat{n}_- \hat{n}_+ \langle 1| + \hat{n}_+ \hat{n}_- \langle 1| \right],
+ |\rangle \langle +| \otimes (\hat{n}_- \hat{n}_+ \langle 1| + \hat{n}_+ \hat{n}_- \langle 1| \right],
\]
where we have defined the coefficients
\[
M_{++}'(T) = \int d^3 p f(p, T) \rho_3^2(p),
M_{+-}'(T) = \int d^3 p f(p, T) \rho_3^2(p) g_s^2(p, m),
M_{-+}'(T) = \int d^3 p f(p, T) \rho_3^2(p) g_s(p, m),
\]
(20)
with \(M_{++}'(T) + M_{+-}'(T) = 1, \ N_3^2(p) (1 + g_s^2(p, m)) = 1,\)
and \(g_s(p, m) = \rho \left( E_s + (-1)^{s+1} m \right)\).

As we admitted that qubit 1 stands for the intrinsic parity of the fermion, we get the correlation density operator for helicity and intrinsic parity as suggested many years ago by Lee and Yang \[7\], in an ad hoc procedure. In that case (c.f. equation (23) from reference \[7\]) the density matrix describes a coherent collection of spinorial particles that exhibit spin and parity as correlated quantum features, through which a suitable interference phenomena between parity doublets is identified. Furthermore, setting \(q = \rho/T\) the Fermi–Dirac distribution can be written as \[7–10\]
\[
f(p, T) = \frac{1}{6\pi^2 (3)} \frac{1}{T} \left( e^{\rho} + 1 \right)^{-1},
\]
(21)
where we have set the Boltzmann constant \(k = 1\) and \(\zeta (3) \approx 1.202\) is a Riemann zeta function. The coefficients (20) can be calculated numerically,
\[
M_{++}'(T_{m}) = \frac{1}{3\pi^2 (3)} \int_0^\infty dq \ q^2
 \times \left( 1 + (-1)^{s+1} \frac{1}{\sqrt{1 + T^2 q^2}} \right) \left( e^{\rho} + 1 \right)^{-1},
\]
with \(k T/m = T_{m} = T/m\) (temperature per unit mass with \(k = c = 1\)). In table 1 we present the values of the \(M_{ij}'\) for different temperatures.

While at very high temperature \(T_m > 10^3\) (for electrons^2, it corresponds to \(T > 10^{12}\) K) we have \(M_{++}'(T_{m}) \approx M_{+-}'(T_{m}) \approx M_{-+}'(T_{m}) \approx 0.5\), the coefficients take, nearly, the same values independently of \(s\); the gas has an equilibrated distribution of intrinsic parity for fermions (\(s = 1\)) and for antifermions (\(s = 0\)). As the temperature reduces, the distributions change. For instance, at \(T_m = 10^{-2}\) (\(T = 10^8\) K) and \(s = 1\), the gas is constituted, overwhelmingly, by positive parity fermions, while for \(s = 0\) it is, mostly, made of negative parity antifermions. The transition probabilities \(M_{ij}'\) are the same at any temperature, and they vanish as the gas cools down. In table 2 we give the differences between the \(M_{ij}'\).

In figure 1 we have drawn the coefficients \(M_{ij}'\) (for fermions) as function of \(T_{m}\), that contain the amount of correlation between the spin and intrinsic parity of a Fermi gas embedded in a thermalized environment. Now we speculate about the meaning of the results. Focusing our attention on the cosmological scenario, the temperature of the universe is a parameter that, roughly, parallels the evolution in time: after the initial surge of a very hot and compact seed of energy, the radiation dominated universe expands and cools down, still keeping the thermalized blackbody frequency distribution. The higher (lower) the temperature the earlier (later) it is its age and size, \(T \propto 1/a(t)\) where \(a(t)\) is the expansion parameter. At quite high temperatures,
become scarcer. As the universe cooled further, say at 10^{-3} \text{ s}, the fermions (and also antifermions) existed with positive and negative intrinsic parity ($M_{++} \approx M_{--} \approx 0.5$), whereas the transition amplitudes, from positive to negative parity, and vice versa, were almost the same. As the universe went on expanding the temperature was reducing, and one parity (positive) began to dominate over the other, $M_{++} \rightarrow 1$, $M_{--} \rightarrow 0$, and the transition amplitude $M_{+} \rightarrow 0$ was reducing too, so the negative parity fermions became scarcer. As the universe cooled further, say at $T_n = 3 \times 10^{-10} \text{ K}$ for $s = 1$, the fraction of negative to positive parity fermions became $10^{-20}$, while the inverse comes out for the $s = 0$ antifermions. At the present epoch the positive parity fermions dominate, constituting the building blocks of the observed universe, while those with negative parity are reduced and only observed from gamma rays produced by cosmic $e^+ - e^-$ annihilation.

By its turn if we consider the negative energy solution ($s = 0$), for the antifermions, the inverse occurs, negative parity prevails at low temperature while the positive parity fermions become quite scarce. So after our calculations the separation between positive parity fermions and negative parity antifermions in the present cold universe finds a plausible explanation.

### 3. Charge conjugation

The charge conjugation operation changes matter into antimatter and it is represented by the operator is $\hat{C} = -i\gamma^5 K \equiv \left(\sigma_1^{(1)} \otimes \sigma_2^{(2)}\right) \hat{K}$, where $\hat{K}$ stands for the complex conjugation operator and $\hat{C}^{-1} = -\hat{C}$. It transforms a Dirac spinor as

$$
\begin{align*}
\begin{pmatrix}
\Psi^C_L(\vec{p}, t) \\
\Psi^C_R(\vec{p}, t)
\end{pmatrix} & \equiv \hat{C}
\begin{pmatrix}
\Psi_L(\vec{p}, t) \\
\Psi_R(\vec{p}, t)
\end{pmatrix} = \left(-i\sigma_2^{(2)}\right) \begin{pmatrix}
\Psi^*_R(\vec{p}, t) \\
\Psi^*_L(\vec{p}, t)
\end{pmatrix}.
\end{align*}
$$

Thus a state is invariant under $\hat{C}$ operation whenever $\left|\Psi^C_L(\vec{p}, t)\right\rangle = -i\sigma_2^{(2)} \left|\Psi^C_R(\vec{p}, t)\right\rangle$ and $\left|\Psi^C_R(\vec{p}, t)\right\rangle = i\sigma_1^{(2)} \left|\Psi^C_L(\vec{p}, t)\right\rangle$. Applying $\hat{C}$ on state (6) one obtains

$$
\begin{align*}
\begin{pmatrix}
\Psi^C_L(\vec{p}) \\
\Psi^C_R(\vec{p})
\end{pmatrix} & = \hat{C}
\begin{pmatrix}
\left|\psi^\dagger(\vec{p})\right\rangle \\
\left|\psi^\dagger(\vec{p})\right\rangle
\end{pmatrix} = \hat{C}
\begin{pmatrix}
\frac{p}{E_p + (-1)^s} \left(\hat{\beta} \cdot \vec{\sigma} \left[\psi^\dagger(\vec{p})\right]_L \right) \\
\frac{p}{E_p + (-1)^s} \left(\hat{\beta} \cdot \vec{\sigma} \left[\psi^\dagger(\vec{p})\right]_L \right)
\end{pmatrix} \\
& = \left(-i\sigma_2^{(2)} \hat{\beta} \cdot \vec{\sigma} \left[\psi^\dagger(\vec{p})\right]_L \right) \\
& \quad + \left(i\sigma_1^{(2)} \left[\psi^\dagger(\vec{p})\right]_L \right),
\end{align*}
$$

implying also the change $s \rightarrow s + 1$. Now, applying $\hat{C}^{-1}$ on the right and $\hat{C}$ on the left of state (19), the coefficients do not change, while $|\pm\rangle \rightarrow |\mp\rangle$ and $|\uparrow\downarrow\rangle \rightarrow |\downarrow\uparrow\rangle$, thus $\hat{C}\rho_{12}^{(10)}\hat{C}^{-1}$ differs from $\rho_{12}^{(10)}$ by the following interchanges $M_{++}^{(s+1)}(T) \approx M_{--}^{(s+1)}(T)$ and $\tilde{n}_+ \approx \tilde{n}_-$, or, fermion $\rho_{12}^{(1)}$ and antifermion $\hat{C}\rho_{12}^{(10)}\hat{C}^{-1}$ interchange roles.

4. The density matrices

The parity-helicity density matrix is

\[
\hat{\rho}_{\chi}^{(s)} = \begin{pmatrix}
M_{++}^{s} (T_m) & 0 & \tilde{n}_{-} M_{-+}^{s} (T_m) & 0 \\
0 & M_{++}^{s} (T_m) & 0 & \tilde{n}_{-} M_{-+}^{s} (T_m) \\
\tilde{n}_{+} M_{+-}^{s} (T_m) & 0 & M_{-+}^{s} (T) & 0 \\
0 & \tilde{n}_{+} M_{+-}^{s} (T_m) & 0 & M_{-+}^{s} (T_m)
\end{pmatrix}
\] (23)

from which we verify that, under the Peres–Horodecki criterion [11, 12], there is no entanglement between intrinsic parity and helicity since the partially transposed matrix, 

\[
\tilde{\hat{\rho}}_{\chi}^{(s)} \equiv \left( \hat{\rho}_{\chi}^{(s)} \right)^{\perp} \cong \chi m \approx -\chi m
\]

so the strength of a transition depends on the mixing angle \( \chi \).

The eigenvalues of intrinsic parity state (24) are

\[
\lambda_{i}^{(s)} = \frac{1}{2} \left( M_{++}^{s} + M_{-+}^{s} \right) + \frac{1}{2} \sqrt{\left( M_{++}^{s} - M_{-+}^{s} \right)^2 + 4 \tilde{n}_{-} \tilde{n}_{+} \left( M_{-+}^{s} \right)^2}
\]

The eigenvalues of intrinsic parity state (24) are

\[
\lambda_{\pm}^{(s)} = \frac{1}{2} \left( M_{++}^{s} + M_{-+}^{s} \right) - \frac{1}{2} \sqrt{\left( M_{++}^{s} - M_{-+}^{s} \right)^2 + 4 \tilde{n}_{-} \tilde{n}_{+} \left( M_{-+}^{s} \right)^2}
\]

that we shall use below. We have omitted the explicit dependence on \( T_m \). The reduced normalized state for the intrinsic parity is

\[
\hat{\tilde{\rho}}_{\chi}^{(s)} = \text{Tr}_{s} \hat{\rho}_{\chi}^{(s)}
\]

\[
= M_{++}^{s} \left\{ |+\rangle \langle +| + M_{-+}^{s} \left| -\rangle \langle -| \right) + M_{-+}^{s} \cos \left( 2\chi \right) \left( |+\rangle \langle -| + |-\rangle \langle +| \right) \right\}
\]

\[
\] (24)

The eigenvalues of \( \hat{\rho}_{\chi}^{(s)} \) are

\[
\lambda_{i}^{(s)} = \frac{1}{2} + \frac{1}{2} \sqrt{\left( M_{++}^{s} - M_{-+}^{s} \right)^2 + 4 \tilde{n}_{-} \tilde{n}_{+} \left( M_{-+}^{s} \right)^2}
\]

By its turn, the normalized density operator for the helicity is diagonal

\[
\hat{\tilde{\rho}}_{\pm}^{(s)} = \text{Tr}_{\pm} \hat{\rho}_{\pm}^{(s)} = H_{++}^{s} \left| 1 \right\rangle \left\langle 1 \right| + H_{-+}^{s} \left| 1 \right\rangle \left\langle 1 \right|
\]

and the coefficients are

\[
H_{++}^{s} = \frac{1}{2} + \frac{\pi}{8} \sin \left( 2\chi \right) \cos \left( \mu \right) \left( M_{++}^{s} (T_m) - M_{-+}^{s} (T_m) \right)
\]

and

\[
H_{-+}^{s} = \frac{1}{2} - \frac{\pi}{8} \sin \left( 2\chi \right) \cos \left( \mu \right) \left( M_{--}^{s} (T_m) - M_{++}^{s} (T_m) \right)
\]

where the non-diagonal term stands for the transition probabilities

\[
\left( |+\rangle \equiv |+\rangle \right) \left( \pm \left| \tilde{\rho}^{(s)} \right| \mp \right) = \left( M_{-+}^{s} (T_m) \right)^2 \cos^2 \left( 2\chi \right)
\]

so the strength of a transition depends on the mixing angle \( \chi \). As the Fermi gas cools, \( \lim_{T_m \to 0} M_{-+}^{s} (T_m) \to 0 \), independently of the value of \( s \) and \( \chi \), so the state decoheres at a lower rate than it takes for the system to reduce the negative \( (M_{-+}^{s} (T_m)) \) or positive parity \( (M_{++}^{s} (T_m)) \) contribution to the mixture. For \( T_m = 10^{-2} \) we find \( M_{-+}^{s} (T_m)/M_{++}^{s} (T_m) \approx 10^{-2} \).

\[ \text{Figure 2. Mutual information } I_{\chi} (T_m) \text{ as a function of the temperature parameter } T_m. \] The plots are for several choices of the mixing angle \( \chi \). Different lines represent different phases: \( \mu = 0 \) (black), \( \pi/4 \) (red) and \( \pi/2 \) (blue). For each \( \chi \) and for different \( \mu \), the curves show very tiny mutual deviations from each other. \( I_{\chi} (T_m) \) decreases to zero at the non-relativistic \( (T_m \to 0) \) limit and increases to its maximal value at the ultra-relativistic \( (T_m \to 1) \) regime.

The von-Neumann entropy of a density operator \( \hat{\rho} \) is defined as \( S(\hat{\rho}) = -\sum_{k} k \ln \left( k \right) \), where \( k \) are the eigenvalues, thus we calculate the mutual information between
intrinsic parity and helicity as
\[ I_{12} (T_m) = \mathcal{H}(\hat{\rho}_1^{(\iota)}) + \mathcal{H}(\hat{\rho}_2^{(\iota)}) - \mathcal{H}(\hat{\rho}_{12}^{(\iota)}). \] (27)
for several values of the mixture angles \( \chi \) and the phase \( \mu \), as depicted in figure 2.

The variation of \( \mu \) implies some very tiny mutual deviations from each other at the transition regime (from UR to NR), i.e., \( \mu \) has no relevant qualitative effect on the mutual information between parity and helicity, thus reinforcing our previous hint for the choice \( \mu = 0 \). As expected, the mutual information \( I_{12} (T_m) \) is insignificant at low temperature, \( T_m \to 0 \), while it is maximal for \( T_m \gg 1 \).

5. Summary and conclusions

It is common knowledge [14] that at the time of the very early universe (\( T \gg 10^2 K \)) the photons had enough energy to become electron–positron pairs, so electrons and positrons existed in thermal equilibrium with radiation. At about 400 000 years after the Big Bang there is change, radiation is free to pass through the universe as its expansion changes it from opaque to transparent. As the universe expanded it cooled, and when the temperature reduced to \( \approx 10^3 \) K photons did not have enough energy to create \( e^- \to e^+ \) pairs, so electrons and positrons were no longer in thermal equilibrium but radiation acquired a thermalized blackbody distribution. A fundamental question is: why did matter (positive intrinsic parity) eventually dominate anti-matter (negative intrinsic parity), which, presumably, were initially on an equal footing? Our calculations and results cannot explain the ‘disappearance’ of the antifermions that existed in the early universe, however it hints of why only the fermions—the quarks and leptons that constitute matter—have positive intrinsic parity (our estimate is \( 10^{20} \) positive for 1 negative parity fermions) and any produced antifermion has a negative intrinsic parity, although the calculations show that at the early universe fermions and antifermions existed in asuperposition of both parities entangled in the helicity states. Otherwise, on the non-relativistic limit the mutual information is null: any quantum correlation between the particle/antiparticle character and the state spin-polarization vanishes. It corresponds to an issue that can be reproduced, from the mathematical point of view, by a FOLDY-WOUTHYUSEN unitary transformation [13]).

Finally, we point out the essentiality of the present framework [4, 5], where it was assumed that the Dirac equation and the spinors describe the dynamics and the state of a massive particle carrying two qubits of information, the helicity and the intrinsic parity. That approach permits quantifying the quantum correlation and the entanglement between the particle/antiparticle degrees of freedom. Moreover, we believe that it might be relevant to discuss the destruction of the ‘mirror’ symmetry (external parity or left/right-handed character) in particle decays involving electroweak interactions, a point that certainly deserves to be scrutinized in subsequent investigations.
