Abstract

By extending our previous isobar model to the $K^0\Lambda$ isospin channel we investigate the properties of the $K^0\Lambda$ photo- and electroproduction at energies near threshold. It is found that the pseudovector (PV) coupling yields significantly larger cross section. Variation of the $K_1$ coupling constants has significant effect only on the PV model. The electromagnetic form factor of the neutral kaon $K^0$ is found to have a sizable effect on the longitudinal cross section of the $K^0\Lambda$ electroproduction near the threshold.

Recently, there has been a great interest in the electromagnetic production of the neutral kaon \( K^0 \). There are several motivations behind this interest, one of them is the search for missing resonances. In the \( K^0 \) photoproduction the \( t \)-channel \( K^0 \) intermediate state does not present due to the lack of the interaction between real photons and neutral mesons. The absence of this channel might have a strong impact on the angular distribution of the predicted observables and also increase the dominance of the nucleon resonance contribution. This situation is obviously different in the leading \( K^+ \Lambda \) and \( K^+ \Sigma^0 \) channels, which for years have become the main source of information on the strangeness production process. Another motivation comes from the deuteron sector, in which the relevant processes are the \( \gamma + d \rightarrow K^0 + \Lambda + p \) and \( \gamma + d \rightarrow K^0 + \Sigma^0 + p \). Due to the lack of the neutron target, the two processes are expected to be the natural avenue in the investigation of kaon photoproduction on the neutron. A recent report shows that the extraction of the elementary cross section is possible for these processes in the quasifree scattering region, where the final state interaction effects are negligible. Note that the result of such an analysis relies on the result of Kaon-Maid model, especially on the \( K^0 \Lambda \) channel. However, the predicted total cross section of this channel is found to be twice larger than that of the \( K^+ \Lambda \) channel, in contrast to the case of other four related isospin channels (see Fig. 1 of Ref. [1]).

There was an attempt to investigate the effect of the \( K^0 \) charge form factor on the \( K^0 \Lambda \) electroproduction. Although significant effects on the longitudinal cross section were observed, the result was found to be very model dependent. Consequently, a reliable phenomenological model becomes the important prescription for this purpose. Since a reliable model should not depend on too many uncertain free parameters, it is obviously important to limit the energy of interest very close to the production threshold.

Very recently, we have analyzed photo- and electroproduction of the \( K^+ \Lambda \) final state at energies near its production threshold by utilizing an isobar model. Using the pseudoscalar (PS) coupling the model can nicely describe experimental data both in the real and virtual photon sectors up to total c.m. energy \( W = 50 \) MeV above the threshold. Using the pseudovector (PV) coupling the agreement with experimental data can still be achieved, although the \( \chi^2 \) per number of data points increases from 0.92 to 1.53.

This paper reports on the extension of our previous model to the \( K^0 \Lambda \) isospin channel. For this purpose we employ the SU(3) symmetry to relate the hadronic coupling constants
of the background terms in the two channels, i.e.,

\[ g_{K^+\Lambda p} = g_{K^0\Lambda n} \]
\[ g_{K^+\Sigma^0 p} = -g_{K^0\Sigma^0 n} \]
\[ g_{V,T}^{K^+\Lambda p} = g_{V,T}^{K^0\Lambda n} \]

(1)

In the \( K^0\Lambda \) production the vector meson exchanged in the \( t \)-channel is the \( K^{*0}(896.10) \) Therefore, the transition moment in \( K^+ \) production, \( g_{K^+\Sigma^0} \), must be replaced by the neutral transition moment by using [4]

\[ g_{K^*0\Lambda\gamma}/g_{K^{*0}\gamma} = -1.53 \pm 0.20 \]

(2)

In the case of the \( K_1(1270) \) vector meson exchange, there is no sufficient information from the Particle Data Book [8]. Thus, we use the value given by the Kaon-Maid [5],

\[ r_{K_1\Lambda\gamma} = g_{K_1\Lambda\gamma}/g_{K^{*0}\gamma} = -0.45 \]

(3)

which was extracted from simultaneous fitting of the \( K^+\Sigma^0 \) and \( K^0\Sigma^+ \) photoproduction data. The \( S_{01}(1800) \) \( u \)-channel stays unmodified, since from Eq. (1) we have \( g_{K^+\Lambda p} = g_{K^0\Lambda n} \), whereas the electromagnetic vertex \( \gamma Y^{*0}\Lambda \) in both \( K^+\Lambda \) and \( K^0\Lambda \) channels is the same.

In the resonance term we have to replace the helicity photon couplings of the proton \( A^p_{1/2} \) with that of the neutron, where [8]

\[ A^n_{1/2} = -0.015 \pm 0.021 \text{ GeV}^{-1/2} \]

(4)

Note that this coupling is substantially smaller than the proton coupling, i.e. \( A^p_{1/2} = 0.053 \pm 0.016 \text{ GeV}^{-1/2} \) [8]. As a consequence, we may expect a relatively smaller resonance contribution in the case of \( K^0\Lambda \) production. This is proven by Fig. 1 where we compare the background and resonance contributions to the total cross section of the \( K^+\Lambda \) and \( K^0\Lambda \) photoproduction. Different from the \( K^+\Lambda \) channel, in which contribution of the \( S_{11}(1650) \) resonance is more or less 20%, contribution of this resonance to the \( K^0\Lambda \) total cross section at \( W = 50 \text{ MeV} \) above threshold is only about 3%.

The predicted \( K^0\Lambda \) total cross sections of both PS and PV models are shown in Fig. 2 where the effects of the variation of the ratio \( r_{K_1\Lambda\gamma} \) given in Eq. (3) are displayed. For the sake of visibility, we have varied this ratio by \( \pm 100\% \) \((\pm 20\%) \) in the PS (PV) model. Both the cross section and the effect are obviously larger in the PV model. We have found that this phenomenon originates from the large \( K_1 \) and \( K^* \) couplings in the PV model. Especially in the case of \( K_1 \), where the coupling constants are around 10 times larger than those in the
PS model. Although we believe that the PS model is still better than the PV one, as in the $K^+\Lambda$ case, an experimental check of the $K^0\Lambda$ total cross section is still mandatory to help to clarify this situation.

The difference between PS and PV models also appears in the differential cross section as shown in Fig. 3. From this figure it is apparent that the dominant role of the $K_1$ and $K^*$ exchanges in the PV model yields not only a large cross section, but also amplifies the bump structure in the angular distribution of differential cross section. Therefore, experimental

\[ W_{\text{thr.}} = 1613 \text{ MeV} \]

\[ \sigma_{\text{tot}} (\mu b) \]

\[ W - W_{\text{thr.}} (\text{MeV}) \]

FIG. 2: (Color online) Total cross sections of the $\gamma + n \to K^0 + \Lambda$ channel predicted by the models using PS (left panel) and PV (right panel) couplings. The shaded area corresponds to the variation of the the ratio $r_{K_1K\gamma}$ in Eq. (3). The PV cross section has been renormalized by a factor of 1/3.
FIG. 3: (Color online) Differential cross sections of the $\gamma + n \rightarrow K^0 + \Lambda$ channel predicted by the models using pseudoscalar (a) and pseudovector (b) couplings.

data of the $K^0\Lambda$ differential cross section can shed more light on the role of the $K_1$ and $K^*$ in kaon photoproduction. From Fig. 3 we can see that both models do not indicate a backward-peaking cross section. This is different from the cross section estimated by the deuteron target [2]. However, we realize that in order to estimate this cross section the ratio $r_{K_1K\gamma}$ is varied [2]. It is important to note here that this ratio is no longer a free parameter if one starts with the elementary process, but it is fixed by the $K^+\Sigma^0$ and $K^0\Sigma^+$ photoproduction channels, for which more experimental data with better statistics are available. Changing the value of $r_{K_1K\gamma}$ will obviously change the predicted observables in the $K^0\Sigma^+$ channel. Furthermore, we also note that the elementary amplitude used to extract the cross section (called SLA in [2]) fits relatively older data. In the previous work [7] we used more recent data and found that the new electroproduction data provide a stringent

constraint to the background, especially to the $K_1$ contribution.

The extension of the PS model to the case of electroproduction has been also discussed in our previous report [7]. Fortunately, experimental data are also available for the $K^+\Lambda$ electroproduction near threshold so that all unknown longitudinal/scalar couplings can be directly extracted. However, this is not the case in the $K^0\Lambda$ electroproduction. Thus, the required scalar photon coupling of the $S_{11}(1650)$ resonance amplitude is taken from the MAID2007 model [10], i.e. $S_{1/2}^n = 0.010 \text{ GeV}^{-1/2}$. The neutron electromagnetic form factors are taken from the Galster parameterization [13], whereas the hyperon form factors as well as the dependencies of the electric and scalar multipoles on the $Q^2$ are assumed to have the same forms as in the $K^+\Lambda$ channel [7].

Compared with other neutral SU(3) pseudoscalar mesons, the neutral kaon has a unique property, i.e. it has an electric or charge form factor. The difference between the strange and non-strange quark masses creates a non-uniform charge distribution in the $K^0$. Consequently, although its total charge is zero, the $K^0$ has an electric or charge form factor. Since the mass difference is still smaller than the mass scale associated with confinement in Quantum Chromodynamics (QCD), $(m_s - m_d) < \Lambda_{\text{QCD}}$, it could lead to a sensitive test of phenomenological models that attempt to describe nonperturbative QCD.

In this paper we do not intent to discuss the form factor in details, instead we will
only employ two relativistic quark models, the light-cone quark (LCQ) model and the quark-meson vertex (QMV) model, in order to find the optimal kinematics where this form factor has the largest effect on the observable. Since contributions of the $K^*$ and $K_1$ exchanges are relatively small in the PS model, contribution of the kaon pole is expected to generate sizable effects on the cross section. The characteristic of these two form factors is exhibited in Fig. 4, where the charge form factor of the neutron $G_E^n(Q^2)$ is also shown for comparison. It is clear from this figure that they have comparable magnitudes. The only difference is that as $Q^2$ increases the two neutral kaon form factors fall off slower than the neutron one.

We note that the inclusion of the $K^0$ form factor is connected with the problem of gauge invariance. In this work we have utilized the Fubini-Nambu-Wataghin term to restore gauge invariance, which is discussed in Ref. [15]. Since the term is very specific and not trivial, we expect that different methods of restoring gauge invariance in this process will not affect the result shown in this work.

The effect of the QMV and LCQ form factors on the separated differential cross sections of the $K^0\Lambda$ electroproduction on a neutron is displayed in Fig. 5, where we have chosen a closer kinematics as in the case of the $K^+\Lambda$ [7], since we expect that with the present technology such a kinematics is experimentally accessible. From this figure it is apparent that the observed effect in the cross section magnitude is consistent with the behavior of the form factors exhibited in Fig. 4, i.e. the LCQ model yields the strongest effect.

The effect of $K^0$ form factors on the unpolarized cross section $\sigma_U$ shown in the upper panels of Fig. 5 seems to be mild, in contrast to the effect on the separated cross sections $\sigma_{TT}$ and $\sigma_{LT}$. Especially in the case of the interference cross section $\sigma_{LT}$ shown in the bottom panels of Fig. 5 where the effect of the LCQ model is predicted to be around 30% at $Q^2 = 0.65$ GeV$^2$. However, we found that the effect is almost negligible on the transversely unpolarized cross section $d\sigma_T/d\Omega$. Therefore, the difference between the three lines shown in this figure originates mostly from the longitudinal cross section $d\sigma_L/d\Omega$. Consequently, we then focus our analysis on the longitudinal cross section. The effects for different values of kaon scattering angle are shown in Fig. 6. It is obvious that the effect is sufficiently large for an experimental check and in fact at the forward angle $\theta_K^{cm} = 25.84^\circ$ and $Q^2 \approx 0.5$ GeV$^2$ the LCQ form factor raises the cross section up to 50%. As explained above, this phenomenon originates from the dominant role of the background terms. From this figure
FIG. 5: (Color online) Separated differential cross sections for the neutral kaon electroproduction $e + n \rightarrow e' + K^0 + \Lambda$ as a function of the kaon scattering angle at $W = 1.65$ GeV and for different values of $Q^2$ (shown in the top panels in unit of GeV$^2$). Solid lines show the calculation with a $K^0$ form factor obtained in the LCQ model while dashed lines are obtained by using the QMV model. The dash-dotted lines are obtained from a computation with the $K^0$ pole excluded. Note that $\sigma_U = d\sigma_T/d\Omega_K + e d\sigma_L/d\Omega_K$, $\sigma_{TT} = d\sigma_{TT}/d\Omega_K$, and $\sigma_{LT} = d\sigma_{LT}/d\Omega_K$.

It is also clear that as the scattering angle increases the effect slightly decreases but still relatively large for the LCQ model at $\theta_K^{c.m.} = 126.87^\circ$. Our finding therefore corroborates the finding of Ref. [6], which used the same form factors [11, 12] as in the present work but with a different isobar model [16]. Experimental data with about 10% uncertainties would be able to resolve the effect of the form factors or even to pin down the appropriate $K^0$ form factor required by the isobar model to describe the $e + n \rightarrow e' + K^0 + \Lambda$ process.

In conclusion we have extended our previous isobar model for the $K^+\Lambda$ channel to include both photo- and electroproduction of the $K^0\Lambda$ by exploiting the SU(3) symmetry and appropriate information from the Particle Data Book. Using this model we have also an-
FIG. 6: (Color online) Longitudinal differential cross section of the neutral kaon electroproduction $e + n \rightarrow e' + K^0 + \Lambda$ as a function of the virtual photon momentum squared $Q^2$ at $W = 1.65$ GeV and for different values of the kaon scattering angles (shown inside the panels). Notation of the curves is as in Fig. 5.

analyzed the differences in the total and differential cross sections obtained by using PS and PV couplings. It is found that the PV model yields significantly larger total and differential cross sections. Needless to say, experimental data on the $K^0\Lambda$ photoproduction are required to check this phenomenon. We have also used the PS model to explore the effect of the $K^0$ charge form factor and found sizable effects on the longitudinal and interference cross sections of the $K^0\Lambda$ electroproduction. Especially in the longitudinal cross section, we found that the effect could raise the cross section up to 50%.
