Opening of the Diamondoid Cage upon Ionization Probed by Infrared Spectra of the Amantadine Cation Solvated by Ar, N₂, and H₂O

Martin Andreas Robert George[1] and Otto Dopfer*[1]

Abstract: Radical cations of diamondoids, a fundamental class of very stable cyclic hydrocarbon molecules, play an important role in their functionalization reactions and the chemistry of the interstellar medium. Herein, we characterize the structure, energy, and intermolecular interaction of clusters of the amantadine radical cation (Ama⁺, 1-aminoadamantane) with solvent molecules of different interaction strength by infrared photodissociation (IRPD) spectroscopy of mass-selected Ama⁺ Ln clusters, with Ln=Ar (n ≤ 3) and Ln=N₂ and H₂O (n = 1), and dispersion-corrected density functional theory calculations (B3LYP-D3/cc-pVTZ). Three isomers of Ama⁺ generated by electron ionization are identified by the vibrational properties of their rather different NH₂ groups. The ligands bind preferentially to the acidic NH₃ protons, and the strength of the NH...L ionic H-bonds are probed by the solvation-induced red-shifts in the NH stretch modes. The three Ama⁺ isomers include the most abundant canonical cage isomer (I) produced by vertical ionization, which is separated by appreciable barriers from two bicyclic distonic iminium ions obtained from cage-opening (primary radical II) and subsequent 1,2 H-shift (tertiary radical III), the latter of which is the global minimum on the Ama⁺ potential energy surface. The effect of solvation on the energetics of the potential energy profile revealed by the calculations is consistent with the observed relative abundance of the three isomers. Comparison to the adamantane cation indicates that substitution of H by the electron-donating NH₃ group substantially lowers the barriers for the isomerization reaction.

Introduction

Amantadine (Ama, 1-tricyclo[3.3.1.1³⁷]decylamine, 1-adamantylamine, 1-aminoadamantane, C₁₃H₁₉NH₂) is the amino derivative of adamantane (C₁₀H₁₉, Ada), the smallest diamondoid.[1] Diamondoids are nm-sized H-passivated nanodiamonds.[2] These rigid, stress-free, and highly stable cycloalkanes form a fundamental class of saturated sp³-hybridized hydrocarbon molecules. Due to their special properties, diamondoids and their derivatives have (potential) applications in a variety of disciplines, ranging from materials and polymer science, molecular electronics, medical sciences, and chemical synthesis to astrochemistry.[3] For example, diamondoids and their radical cations are predicted to be abundant in the interstellar medium, and since several amines have been already detected,[4] the presence of Ama and its cation is expected as well.[5] On the other hand, radical cations of diamondoids are frequently involved as intermediates in substitution reactions occurring in polar solvents.[4,6] Despite its high stability, functionalization of Ada and higher diamondoids can readily be carried out, making several derivatives accessible.[6,7]

One of the most important diamondoid derivatives is Ama, because it has widespread pharmaceutical applications as antivirus and anti-Parkinson drug and thus is successfully marketed under several brand names, including Symmetrel® (Ama·HCl), Gocovri®, Symadine®, and Osmolex ER®.[3d,8] Ama is effective in the prophylaxis and treatment of influenza A infections, because it prevents the virus from entering the host cell by blocking the ion channel.[9] Due to drug resistance, however, its use is no longer recommended for influenza.[10] Although the mechanism of action as anti-Parkinson drug is not yet fully understood, it increases the release of dopamine from the nerve endings of brain cells and stimulates the noradrenaline response.[11] In addition, Ama has NMDA receptor antagonistic effects[12] and is discussed for treatment of other diseases such as multiple sclerosis, depression, and cocaine addiction.[13] In 2013, the methylated derivative (memantine, Namenda®) was among the top 100 drugs sold worldwide, with sales of more than 10$ billion.[14]

In Ama (C₁₀), the H atom of one of the four CH groups of Ada (T₁) is replaced by an NH₂ group, thus preserving most of the special chemical properties of diamond-like structures.[2b,15] The vibrational, electronic, and geometric properties of Ama have been determined by Raman, infrared (IR), and electron momentum spectroscopy.[16] In addition, the interaction be-
tween Ama and DNA was investigated by Raman spectroscopy. Unlike neutral Ama, there have been only very few studies of the Ama− radical cation, the target of the present work. Low-resolution electron momentum spectra show that ionization of Ama into the electronic ground state of Ama− occurs by removal of an electron from the nonbonding lone pair of the NH₂ group, with a rough estimate of the vertical ionization energy of 8.6 eV. Early mass spectrometric studies of 1-substituted derivatives of Ada have suggested opening of the adamantyl cage by breaking the C−C bond adjacent to the substituent, with the major fragmentation channel for Ama− being elimination of C₂H₄ leading to the formation protonated aniline.

Compared to Ama−, considerably more information is available for the Ada− parent cation, which has been characterized by photoelectron, photoionization, and fragmentation spectroscopy, IR and electronic photodissociation (IRPD, EPD) spectroscopy, and quantum chemical calculations. [19c,20,24] IRPD spectra of Ada− with L=He, N₂, H₂O indicate Jahn-Teller distortion and C−H bond activation upon ionization into the cation ground state. [19n,20] Significantly, all transitions observed could be assigned to cluster isomers composed of the nascent cage structure of Ada−, consistent with low-resolution EPD spectra of bare Ada− generated by electron ionization (EI). [24] Due to vertical ionization given by the Franck-Condon principle, photoelectron and photoionization spectra of Ada only probe the vibronic structure of the nascent cation geometry and thus detect solely the canonical cage structure of Ada−. [19n,20] Fragmentation mass spectra of Ada− generated by VUV and XUV photoionization as well as EI indicate substantial fragmentation. [19e,f,n] Interestingly, quantum chemical analysis of the involved fragmentation processes postulate stable open-cage isomers of Ada− as local and even global minima on the potential energy surface as reaction intermediates prior to fragmentation, although experimental evidence for such minima has not been presented. [19m,n] In the condensed phase, diamonoid derivatives with open-cage structures have been prepared by chemical reactions. [21] Such species are of interest, because they are well suited for complexation with transition metals. [22] Studying the open process of diamonoid cages is also of interest for understanding chemical reactions in which cage opening and reclosing occurs. To this end, it has been shown that a reaction of 1-hydroxymadinantane with elemental bromine leads to consecutive opening and reclosing of the cage, providing straightforward access to a class of previously unknown 1,2-disubstituted diamonoid derivatives. [23] However, in none of the condensed-phase studies, the open-cage intermediates could be trapped or detected as stable cations.

With the major goal of characterizing the ionization-induced cage-opening process of diamonoid cations in the gas phase, we analyze herein IRPD spectra of size-selected Ada−L clusters with L=Ar (n=1−3), L=N₂ (n=1), and L=H₂O (n=1) generated in an El source by means of dispersion-corrected density functional theory (DFT) calculations at the B3LYP−D3/cc-pVTZ level. Ama− was chosen for the study of rearrangement processes of the adamantyl cage (C₉H₁₈) upon ionization for the following reasons. Our previous studies on Ada−L and Ama−(H₂O)₃ using the same experimental and computational approach indicate that, as a result of H−NH₂ substitution, one of the C−C bonds of Ama− is substantially less stable and highly activated compared to Ama−. [19g,20,24] Thus, Ama− has a strongly reduced barrier to cage opening which may thus be observable. Indeed, ionization of Ama into its cation ground state occurs by removal of an electron from the nonbonding N lone pair rather than from a bonding C−C σ orbital completely delocalized over the cycloalkane cage in Ada−. Within the ligand series Ar < N₂ < H₂O, we tune the type and strength of the interaction of the solvent molecules with Ama−. While Ar will only weakly interact with Ama− via dispersion and induction (charge-induced dipole), the interaction of N₂ will be somewhat stronger due to additional electrostatic charge-quadrupole forces, as has previously been shown for related amine cation clusters (such as aniline− and 4-aminobenzonitrile−). [23] On the other hand, H₂O will form a strong NH⋯O ionic hydrogen bond (H-bond) to Ama− based mostly on electrostatic charge-dipole interaction. [24,24] Thus, the weak interaction of Ar and N₂ with Ama− is expected to have only a negligible influence on the structural isomers and the rearrangement process of the Ama− core ion, while its strong interaction with H₂O may substantially perturb the potential energy surface of the Ama− cage-opening reaction. In a recent letter [24] we have already reported a preliminary analysis of the IRPD spectrum of the Ama− Ar dimer (n=1), and the main results may be summarized as follows. In addition to the canonical nascent Ama− isomer with an intact C₉H₁₅ cage (I, ~50%), we could unambiguously identify two distonic bicyclic iminium isomers in which the adamantyl cage opens upon ionization (II/III, ~15/35%), whereby III is in fact lower in energy than the canonical cage isomer I (Figure 1 and 2). Moreover, we determined the reaction profile with barriers and intermediates along this cage-opening reaction by DFT calculations and rationalized their relative abundance. In the present work, we provide a full account of this cage-opening process by presenting and analyzing the IRPD spectra of larger Ama−Ar series clusters (n ≤ 3) and Ama−L dimers with L=N₂ and H₂O to determine the effect of solvent molecules with different binding energy on the reaction profile. In fact, we have studied previously the microhydration process of Ama− by IRPD and DFT of Ama−(H₂O)ₙ clusters up to n ≤ 3. [24] While the results gave a first impression of the structure and IR spectrum of bare Ama− and the microhydration structure of the cage isomer (I), no evidence of the open-cage bicyclic isomers was found. [24] To this end, we report herein a new IRPD spectrum of Ama−H₂O with an improved signal-to-noise ratio, which allows us to identify also the open-cage structures of Ama−H₂O (II/III). We also briefly discuss why the cage-opening process is suppressed for Ama− and its clusters based on the effect of H−NH₂ substitution on the potential energy profile.

**Experimental and Computational Techniques**

IRPD spectra of Ama−Lₙ clusters are obtained in a quadrupole tandem mass spectrometer coupled to an El cluster source and...
an octupole ion trap. Cold Ama\(^{+}\) \(\text{L}_n\) clusters are generated in a pulsed supersonic plasma expansion by electron and/or chemical ionization of a heated Ama sample (Sigma Aldrich, > 97\%, \(T \sim 130^\circ\)) seeded in a suitable carrier gas (Ar or \(\text{N}_2\), 10–20 bar stagnation pressure) close to the nozzle orifice and three-body clustering reactions. For the generation of Ama\(^{+}\) \(\text{H}_2\text{O}\) clusters, a

Figure 1. Calculated equilibrium structures (in Å and degrees) of Ama\(^{+}\) \(\text{I–III}\) and \(\text{I–III-L}\) with \(\text{L=Ar, N}_2\), and \(\text{H}_2\text{O}\) in their ground electronic state (B3LYP–D3/ cc-pVTZ). The numbering of C atoms is indicated by red numbers. Intermolecular bond lengths and angles are indicated by red values.
small amount of distilled water is added to the gas inlet system. The filaments of the EI source are operated at an offset voltage of up to 200 V, which provides the upper limit for the kinetic energy of the electrons hitting the molecular beam. These electrons are (inelastically) scattered by collisions with atoms/molecules in the high-pressure region of the expansion and produce secondary electrons by ionization events. Ama\textsuperscript{+} ions are then generated either by EI with primary or secondary electrons or by chemical ionization (e.g., Penning ionization or charge transfer with excited or ionized carrier gas). As a result of these complex processes in the plasma expansion, the initial excess ionization energy deposited in Ama\textsuperscript{+} upon ionization is not well characterized. The generated Ama\textsuperscript{+} and resulting fragment ions are cooled by collisions and form clusters by three-body aggregation. The upper limit of the internal energy (and thus the effective temperature) of the generated Ama\textsuperscript{+} clusters is then given by the dissociation energy of the ligands, which increases in the order Ar < N\textsubscript{2} < H\textsubscript{2}O. After mass selection by the first quadrupole, the desired parent cluster ion is irradiated in the adjacent octupole with a tunable IR laser pulse (ν\textsubscript{IR}) of an optical parametric oscillator (10 Hz repetition rate, < 4 cm\textsuperscript{-1} bandwidth) pumped by a nanosecond Q-switched Nd\textsubscript{3}YAG laser. The IR laser is characterized by a pulse energy of 2–5 mJ in the 2600–3800 cm\textsuperscript{-1} range and 0.1–0.5 mJ in the 1200–1800 cm\textsuperscript{-1} range. The laser frequency is calibrated using a wavemeter. Resonant vibrational excitation of the cluster ions causes the loss of all ligands in the size range investigated. The produced Ama\textsuperscript{+} fragments are selected by the second quadrupole and monitored by a Daly detector as a function of laser frequency to obtain IRPD spectra of Ama\textsuperscript{+} clusters. The ion source is irradiated in the adjacent octupole with a tunable IR laser pulse by the first quadrupole, the desired parent cluster ion is selected, and the generated Ama\textsuperscript{+} ions are cooled by collisions and form clusters by three-body aggregation. The upper limit of the internal energy (and thus the effective temperature) of the generated Ama\textsuperscript{+} ions is determined from fitting the NH\textsubscript{3} bending frequency of the related aniline cation to the experimental value of the NH\textsubscript{3} bending overtone.\textsuperscript{[25b]} The use of three scaling factors accounts for the somewhat different anharmonicities of the various stretching and bending modes.\textsuperscript{[27]} Computed IR stick spectra are convoluted with Gaussian line profiles (fwhm = 10 cm\textsuperscript{-1}). In a few cases, anharmonic vibrational calculations are performed to estimate frequencies and IR intensities of overtones and combination bands.\textsuperscript{[29]} Natural bond orbital (NBO) analysis is used to evaluate the charge distribution, charge transfer, and spin density.\textsuperscript{[30]} A complete set of all relevant structures (Figure S2–S5), NBO charge and spin data (Figure S6–S13), computed and experimental IR spectra (Figure S14–S33, Tables S1–S6), potential energy surfaces (Figure S35), and HOMO orbitals (Figure S35–S36) are given in the Supporting Information, along with Cartesian coordinates and energies (Tables S7–S13), while the most important information is presented in Figure 1 and 8 and Table 1.

**Experimental Results**

Typical mass spectra of the EI source are shown in Figure S1. The major observed fragments of the parent Ama\textsuperscript{+} ion (m/z 151) occur at m/z 136, 108, 94, and 57. These are consistent with the standard EI mass spectrum of Ama and confirm the parent ion as Ama\textsuperscript{+}, with protonated aniline (m/z 94) being the most intense fragment ion.\textsuperscript{[19b,19c]} In addition, different clusters of Ama\textsuperscript{+} and its fragments with neutral ligands (L=Ar, N\textsubscript{2}, H\textsubscript{2}O, Ama) are generated in the supersonic plasma expansion. CID spectra of size-selected Ama\textsuperscript{+}L\textsubscript{n} cluster ions show merely the loss of neutral ligands, confirming the composition of the clusters and ruling out any isobaric contamination (Figure S1).

The IRPD spectra of all investigated Ama\textsuperscript{+}L\textsubscript{n} clusters recorded in the XH stretch range (2700–3800 cm\textsuperscript{-1}) are
compared in Figure 3, while the IRPD spectrum of Ama$^+$Ar obtained in the fingerprint range (1200–1800 cm$^{-1}$) is shown in Figure 4. The positions and widths of the transitions observed are listed in Table 1, along with the suggested vibrational and Isomer assignments derived from the DFT calculations. The IRPD spectrum of Ama$^+$Ar was reported and partially analyzed before$^{[23]}$ while the Ama$^+$H$_2$O spectrum in Figure 3 provides an improved spectrum over the one reported earlier, with more discernible features not identified previously (Table 1).

Table 1. Positions, widths (FWHM in parenthesis) and vibrational and Isomer assignments of the transitions observed in the IRPD spectra of Ama$^+$Ar, Ama$^+$N$_2$, and Ama$^+$H$_2$O (Figure 3 and 4).$^{[a]}$

[a] All values are given in cm$^{-1}$. [b] Stretching ($\nu$), bending ($\beta$), torsion ($\tau$), wagging ($\gamma$), rocking ($\rho$).
herein for the first time ($L_{2/3}$, $M_{2/3}$) due to the higher signal-to-noise ratio achieved.

The $N$ and $O$ bands at 3627 and 3717 cm$^{-1}$ are solely observed for Ama$^{+}$H$_2$O and readily assigned to free $\nu_{\text{OH}}$ modes of the H$_2$O ligand.\[24\] Their red-shifts of 30 and 39 cm$^{-1}$ from the corresponding transitions of bare H$_2$O (3657 and 3756 cm$^{-1}$) are typical for cation-H$_2$O complexes with charge-dipole configuration, in which the O atom of H$_2$O is pointing toward the positive charge.\[24,26\] The relatively large width of these two transitions suggests that the $\nu_{\text{OH}}$ modes of the assigned isomers I–III are not resolved.

Except for the Ama$^{+}$H$_2$O spectrum, the IRPD spectra of all Ama$^{+}$L$_n$ clusters have very similar appearance in the CH stretch range, with respect to both frequencies (to within 13 cm$^{-1}$) and relative IR intensities for the $\nu_{\text{CH}}$ stretch fundamentals of Ama$^{+}$ (A–F). The spectra are better resolved for Ama$^{+}$Ar$_{2/3}$ because larger clusters are colder. For Ama$^{+}$H$_2$O, the CH stretch range is strongly affected by the red-shifted and broadened $\nu_{\text{NH}}$ transition of the NH...O ionic H-bond, which carries high IR oscillator strength and thus is involved in NH/CH stretch local mode mixing and anharmonic interactions (e.g., Fermi resonances with CH and CC overtones and combination bands).\[24,26,43,31\]

Apart from the transitions readily attributed to NH, OH, and CH stretch fundamentals, the IRPD spectra display in the XH stretch range transitions with less obvious assignments. For example, band H near 3150 cm$^{-1}$ for Ar shifts gradually to the blue for ligands with stronger interaction (3172 and 3187 cm$^{-1}$ for N$_2$ and H$_2$O), and the same trend is observed for peak I (3267, 3282, 3318 cm$^{-1}$ for Ar, N$_2$, H$_2$O), indicating that these bands are combination or overtone transitions including the bending, scissoring, or wagging motions of the NH$_2$ group. H-bonding with L generates an additional retarding force for these NH$_2$ modes and thus to higher frequencies for stronger NH...L bonds. The weak and tentative band U ($\sim$3103 cm$^{-1}$) is only observed in the Ama$^{+}$Ar spectrum, while the very weak feature G ($\sim$3010 cm$^{-1}$) is only resolved in the Ama$^{+}$Ar and Ama$^{+}$N$_2$ spectra. Moreover, an additional peak V is observed only for H$_2$O at 3213 cm$^{-1}$, suggesting an assignment to a combination or overtone of the H$_2$O bend ($\beta_{\text{OH}}$).

The fingerprint range is considered only for Ama$^{+}$Ar, with the main purpose of confirming the number of Ama$^{+}$ isomers inferred from the NH stretch range.\[27\] Indeed, the fingerprint spectrum of Ama$^{+}$Ar is dominated by three intense, narrow, and isolated peaks in the NH$_2$ bending range (1599, 1664, 2067 cm$^{-1}$) with the relative intensities of 3:2:1. The positions and widths of the transitions observed (A–K) are listed in Table 1, along with their vibrational and isomer assignments.

Figure 3. IRPD spectra of Ama$^{+}$L$_n$ (L=Ar, N$_2$, H$_2$O) in the XH stretch range recorded in the Ama$^{+}$ channel. The positions and widths of the transitions observed (A–K) are listed in Table 1, along with their vibrational and isomer assignments.

Figure 4. IRPD spectra of Ama$^{+}$Ar in the XH stretch and fingerprint ranges compared to linear IR absorption spectra of Ama$^{+}$ (I–III) calculated at the B3LYP–D3/cc-pVTZ level (reproduced with permission from Ref. [27], copyright 2022 American Chemical Society). The positions of the transitions observed and their vibrational and isomer assignment are listed in Table S2. Relative energies ($E_0$) are given in kJ mol$^{-1}$.
1717 cm\(^{-1}\)) assigned to \(\beta_{\text{NHI}}\) (scissoring mode) of I–III (Q1–Q3). There are four other, weaker, and broader peaks R, S, P, and T observed in the range of the \(\beta_{\text{CH2}}, \gamma_{\text{CH2}}, \gamma_{\text{CH3}}, \text{and }\gamma_{\text{CH}}\) modes, whose detailed assignment has to rely on the DFT calculations. As these bands turn out not to be isomer-specific (apart from T), we do not consider them in detail further. Significantly, the fingerprint spectrum of Ama\(^+\)Ar suggests H and I to be overtones of Q1 and Q2, while the corresponding overtone of Q3 is probably hidden in the dense NH stretch range.

**Computational Results and Discussion**

The very similar IRPD spectra of Ama\(^+\)Ar, suggest only a minor impact of the Ar ligands on the properties of the Ama\(^+\) core ion. To this end, the Ama\(^+\)Ar spectrum has previously been used to identify the three relevant Ama\(^+\) isomers I–III,[27] mostly by the different properties of their NH\(_2\) group resulting in rather different \(v_{\text{NH2}}\) and \(\beta_{\text{NHI}}\) frequencies. Hence, we briefly summarize the computational results for I–III and compare them to the experimental Ama\(^+\)Ar spectrum. Subsequently, we will discuss the effects of the ligands on the structural, vibrational, and energetic properties of I–III and finally evaluate the effect of H–NH\(_2\) substitution.

**Ama\(^+\) isomers I–III**

A potential energy diagram for the ionization-induced rearrangement reaction of Ama is shown in Figure 2. Vertical ionization of neutral Ama (A', C) leads to the nascent cage isomer I of the Ama\(^+\) radical cation (A'\(^+\), C\(_r\), \(E_s = 45.9\) kJ mol\(^{-1}\)). This ionization process activates one of the C–C bonds, which readily breaks and then leads through cage opening to the formation of the bicyclic distonic isomer II (A'\(^+\), C\(_r\), \(E_s = 87.4\) kJ mol\(^{-1}\)) via transition state TS(I–II) located at a barrier of \(V_{\text{mi}} = 54.1\) kJ mol\(^{-1}\) for the forward reaction. A subsequent 1,2 H-shift then forms via TS(II–III) at \(V_{\text{mi}} = 81.6\) kJ mol\(^{-1}\) the most stable isomer III (A'\(^+\), C\(_r\), \(E_s = 0\) kJ mol\(^{-1}\)) which is also a distonic ion and 45.9 kJ mol\(^{-1}\) more stable than the nascent cage isomer I. The structures along with the atomic numbering of neutral Ama and the three Ama\(^+\) isomer I–III are compared in Figure 1 (and S2), while partial charges and electron spin densities are listed in Figure S6 and S7. The computed IR spectra are plotted in Figure 4 (and S14), while relevant vibrational frequencies are listed in Tables S1 and S2.

In neutral Ama, the NH\(_2\) group is attached in a pyramidal configuration (sp\(^3\) hybridization of N) to the C\(_9\)H\(_{15}\) cage via a C–N single bond (\(r_{\text{CN}} = 1.467\) Å). H–NH\(_2\) substitution has little impact on the geometry of the C\(_9\)H\(_{15}\) cage, with a minor but noticeable activation of the C1–C3 bond adjacent to the NH\(_2\) group in the C\(_r\) symmetry plane (1.544 vs. 1.538 Å, see Figure S4 for the structure of Ada). In general, the calculated structure and IR spectrum of Ama agree well with previous computational and experimental data.[16b–e] Ionization of Ama into its ground electronic state by removal of an electron from the N lone pair orbital of the NH\(_2\) group (HOMO, Figure S35) results in the formation of isomer I of Ama\(^+\). Due to orbital conjugation and charge delocalization, the partial charge on the NH\(_2\) group increases by 0.474 e, the C–N bond order increases from 1 to ~1.5 (\(r_{\text{CN}} = 1.384\) Å), the pyramidal NH\(_2\) group becomes essentially planar (similar to ionization of NH\(_3\)), and the NH\(_2\) angle increases from 106° to 117° (sp\(^2\) hybridization of N). The N–H bonds contract by 3 mÅ, resulting in substantial blue-shifts in the NH stretch frequencies upon ionization (\(\Delta\nu_{\text{CN}} = 40/80\) cm\(^{-1}\), Figure S14). As a result of the higher positive partial charges on the NH protons (\(q_{\text{NH}} = 0.405\) e), the IR intensities of the \(\nu_{\text{NH}}\) fundamentals are enhanced by 2–3 orders of magnitude. This effect is crucial because detection of the \(\nu_{\text{NH}}\) bands of Ama\(^+\)L\(_2\) is essential for isomer identification. Significantly, ionization of Ama has also a strong impact on the C–C bonds lying in the C\(_r\) symmetry plane due to conjugation with the NH\(_2\) lone pair. In particular, the C1–C3 bond adjacent to the NH\(_2\) group, already slightly activated by 6 mÅ in neutral Ama by H–NH\(_2\) substitution and eventually breaking when the cage opens to form isomer II, is further strongly destabilized and elongated by 153 mÅ upon ionization. The adjacent C3–C9 bond in the C\(_r\) plane shortens by merely 16 mÅ due to the increased distance from the N lone pair, while all other C–C bonds of the cage remain almost unchanged. Ionization increases the spread in the C–H bond lengths (\(\Delta r_{\text{C\text{--H}}} = 8\) vs. 3 mÅ), resulting in a more pronounced splitting of the intense convoluted and mostly unresolved doublet band of the CH\(_3\) stretch modes of Ama (2890 and 2917 cm\(^{-1}\)) into four better resolved single bands at 2840, 2920, 2955, and 3024 cm\(^{-1}\). The NH\(_2\) bending mode (\(\beta_{\text{NHI}}\)) is slightly red-shifted by 14 cm\(^{-1}\) to 1595 cm\(^{-1}\), and its IR intensity increases by a factor of 2. As a result, it becomes the most intense fundamental in the fingerprint range, and this aspect is again crucial because, in addition to \(\nu_{\text{NH}}\) also the \(\beta_{\text{NHI}}\) mode provides a sensitive probe of the isomeric structure of Ama\(^+\). Due to substantial charge delocalization from NH\(_2\) to C\(_9\)H\(_{15}\), the adamantyl cage carries most of the excess positive charge (\(q_{\text{CHx}} = 0.867\) e, \(q_{\text{NH2}} = 0.313\) e), whereby the acidic NH protons (\(q_{\text{NH}} = 0.405\) e) still serve as attractive proton donors for H-bonds with neutral ligands. Finally, the adiabatic ionization energy of IE = 7.95 eV predicted for I is consistent with the rough estimation for the vertical value of 8.6 eV obtained from a low-resolution electron momentum spectrum.[16b]

The bicyclic open-cage isomer II is formed from I by breaking the strongly activated C1–C3 bond. At the same time, the cyclohexane ring is converted from the chair into the boat configuration. As a result, the C1…C3 distance of the broken bond increases to 4.650 Å, while the \(\theta_{\text{C1C3C2}}\) angle in the C\(_r\) plane opens from 39.2° to 125.1°. This structural rearrangement forms a CH\(_x\)* radical site and a C–N double bond (\(r_{\text{CN}} = 1.295\) Å), and is accompanied by a separation of charge and spin. The spin density of this distonic iminium ion is located on the CH\(_x\)* radical site (\(S_C = 1.005\)) while the positive charge is mostly localized at the CNH\(_2\) charge site (\(q_{\text{Ch2}} = 0.754\) e). While the C–C bonds to the CH\(_x\)* and CNH\(_2\) groups strongly contract (\(\Delta r_{\text{C\text{--X}}} = -36\), \(\Delta r_{\text{C1C2}} = -56\), \(\Delta r_{\text{C2C3}} = -6\) mÅ), the other C–C bonds are elongated upon the chair—boat transformation (\(\Delta r_{\text{C\text{--C}}} = 30\), \(\Delta r_{\text{C1C2}} = 17\), \(\Delta r_{\text{C2C3}} = 12\) mÅ). The largest changes in the C–H bond lengths occur on the CH\(_x\)* group (+6 mÅ), while
all others change less than 3 mÅ. As a result of cage opening, the ν_CCH modes of II are more spread than for I, with three convoluted bands at 2901, 2926, and 2972 cm⁻¹ and weaker high-frequency ν_CCH modes of CH₂⁺ at 3021 and 3121 cm⁻¹. The ν_CCH mode is red-shifted down to very low frequency (2821 cm⁻¹) and has lost almost all IR activity. Due to the increase in C–N bond order, the CNH₂⁺ group in II is even more planar than in I, and as a result β_HNdicouples strongly with the blue-shifted ν_CCN mode, leading to a very intense and blue-shifted β_HNdic band at 1670 cm⁻¹ and a weak ν_CCH band at lower frequency (1542 cm⁻¹). In line with the minor changes in the N–H bond lengths (≤1 mÅ), ν_HNdis exhibit small shifts of +7/−5 cm⁻¹. The slightly larger positive charge on the NH₂ protons (q_HN=0.421 e) makes this binding site for neutral ligands even more attractive than in I.

The bicyclic open-cage isomer III is formed from II by a 1,2-H-shift from C9H to the terminal CH₂⁺ group. As a result, the primary radical II (CH₃⁺) is transformed into a more stable tertiary radical III (CR₃⁺), which thus becomes by far the global minimum on the Ama⁺ potential (Figure 2). This CR₃⁺ radical group becomes nearly planar (sp² hybridization of C9) with bond angles of 121.2° and 115.8°, while the terminal CH₃ group becomes pyramidal (sp³ hybridization of C3) with bond angles of 106.3° and 109.5°. Parallel to the H-shift, the cyclohexane ring changes back from boat to chair. As a result, the C₁…C₃ distance contracts again to 3.346 Å and θ_C1OOC decreases slightly to 106.1°. Interestingly, there is substantial orbital overlap between the 2p orbital of the C9R₁ radical center and the 2π orbital of the C–N double bond (as indicated by the HOMO, Figure S35), consistent with the short C₁…C₉ separation of 2.616 Å and the slightly pyramidal structure of the C9R₁ group. The C–C bonds of the CR₃⁺ group and the Cₙ–Cₙ bond to the new CH₃ group contract by 51 and 4 mÅ, respectively. Upon boat−chair back transformation, the C–C bonds adjacent to the NH₂ group as well as their corresponding parallel C–C bonds are stretched again (Δr_C=C=11, Δr_C=C=5 mÅ), while the other C–C bonds contract again (Δr_C=C=−23, Δr_C,C=−12 mÅ). The C–H bonds of the former CH₂⁺ radical group are stretched again to a value typical for CH₂ bonds (1.091 Å), and most other C–H bonds are also slightly elongated (Δr_C–H=2 mÅ). As a result, the ν_CCH and ν_CCH fundamentals move again closer together and form two weak bands at 2878 and 2926 cm⁻¹ and one intense band at 2961 cm⁻¹. Of course, the low-frequency acidic ν_CCH mode of II/III at 2821/2840 cm⁻¹ disappears. Compared to II, the C–N double bond of III is slightly elongated to 1.315 Å, while the N–H bonds contract from 1.012 to 1.009 Å. As a result of the shortest N–H bonds of all three Ama⁺ isomers, the NH₂ stretch modes have the highest frequencies (ν_HNdis=3358/3467 cm⁻¹). Similar to II, β_HNdic of III couples to ν_CCH, resulting in β_HNdic at 1641 cm⁻¹ and ν_CCH at 1500 cm⁻¹. Both modes gain, however, in IR intensity, and this effect is more pronounced for the ν_CCH band (factor ~20). The β_CCH/β_CCH band at 1440 cm⁻¹ also gains in intensity due to the newly formed C₉H group in III. Similar to II, III is also a distonic iminium ion, with spin density located on the CR₃⁺ radical site (ρ₀=0.627) and positive charge localized at the CNH₂ site (q_CNH₂=0.608 e). The similarly high positive partial charge on the NH₂ protons (q_HN=0.411 e) makes this binding site of III also very attractive for neutral ligands.

Comparison of the experimental Ama⁺ Ar spectrum to the IR spectra computed for the three monomer isomers I–III in Figure 4 demonstrates the presence of all three Ama⁺ isomers, in particular the observation of six ν_HN (ν₁,ν₂; ν₂,ν₃) and three β_HNdic bands (Q₁, Q₂). A detailed vibrational and isomer assignment is listed in Table S2. Based on relative intensities and frequencies, the three pairs J₁/K₁, J₂/K₂, and J₃/K₃ are readily assigned to ν_HNdis of I–III, with a maximum, mean, and median deviation of 23, 14, and 16 cm⁻¹ between measured and computed frequencies, respectively. These differences are consistent with the widths of the bands (12±4 cm⁻¹) and possible effects of Ar-tagging (computed to be ≤10 cm⁻¹). Concerning the β_HNdic bands (Q₁), a very good match is obtained for isomer I between experiment and prediction (Δν_HNdic=4 cm⁻¹ for Q₁). The agreement for the distonic isomers II and III for the corresponding β_HNdic modes is somewhat worse (23 and 47 cm⁻¹ for Q₂ and Q₃), probably due to the strong coupling between β_HNdic and ν_CCH which may not be accurately described by a single scaling factor for both types of modes (different anharmonicity and bond order for ν_CCH). Nonetheless, the direction and magnitude of these β_HNdic band shifts upon this coupling are reproduced reasonably well. Actually, band T at 1551 cm⁻¹ may be assigned to the intense ν_CCH mode of III predicted at 1500 cm⁻¹.

By considering the achieved signal-to-noise ratio and the calculated and observed IR intensities (peak area) of peaks Q₁, the relative population of the isomers I, II, and III can be roughly estimated as 50, 15, and 35 % (or 10 : 3 : 7), respectively. For this estimate, we assume similar Ar complexation efficiencies for I–III, which is justified by their similar Ar binding energies. Such a population ratio is also consistent with the relative intensities in other spectral ranges, although these are more congested and thus less suitable for a reliable quantitative analysis.

In contrast to the range of the rather isolated ν_HN and β_HNdic modes, where a clear-cut assignment to the individual isomers I–III is feasible due to their rather different NH₂ properties, the isomer assignment in the other spectral ranges is less obvious due to similar vibrational frequencies and increased spectral congestion. Nonetheless, the observed IRPD spectrum is consistent with the presence of all three Ama⁺ isomers. For example, in the CH stretch range, bands B–D (2864, 2920, 2947 cm⁻¹) can be attributed to the single and isolated ν_CCH mode and overlapping ν_CCH modes predicted at 2840, 2920, and 2955 cm⁻¹ for the predominant I isomer, respectively. Similarly, E (2599 cm⁻¹) and F (2978 cm⁻¹) can be interpreted as ν_CCH modes (2961 and 2971 cm⁻¹), while band G (3008 cm⁻¹) can be assigned to the single ν_CCH mode of 3024 cm⁻¹ of the special CH₂ group adjacent to the elongated C₁–C₃ bond of I. Thus, while most CH stretch bands may readily be explained by the most abundant isomer I, there are several indications for the presence of II and III in this spectral range as well. For example, the weak peak A at 2842 cm⁻¹ provides strong evidence for isomer II, because for I and III no such low-frequency CH stretch band is predicted. In addition, the high relative intensity of band D is not reproduced.
by the simulation for I and is thus indicative for a significant population of III. While the appearance of bands R, S, and P in the Ama\(^{+}\)Ar spectrum is consistent with the predictions of all three isomers, the well isolated transitions H and I at 3151 and 3267 cm\(^{-1}\) are not reproduced by the calculated spectra of any of the isomers. Hence, they are attributed to overtones and combination bands of modes occurring in the fingerprint range, which are not included in the (scaled) harmonic calculations. Indeed, strong overtone transitions of the scissoring mode (2\(\nu_{\text{NH}}\)) have been detected in the IR spectra of a variety of amine radical cations, such as (substituted) anilines.\(^{25,32}\) Following this likely scenario, bands H and I at 3151 and 3267 cm\(^{-1}\) are attributed to 2\(\nu_{\text{NH}}\) of isomers I and III, with their \(\nu_{\text{NH}}\) fundamentals being bands Q1 and Q2 (1599 and 1664 cm\(^{-1}\), respectively). The corresponding 2\(\nu_{\text{NH}}\) overtone of isomer II is estimated near 3400 cm\(^{-1}\) from the fundamental band at 1717 cm\(^{-1}\) (Q3) and thus hidden by the dense and intense NH stretch bands. Anharmonic calculations actually predict significant intensities of such 2\(\nu_{\text{NH}}\) bands for I–III and thus support this assignment (Tables S2–S3).

\textbf{Ama}\(^{+}\)Ar\(_n\) clusters

The assignment of the Ama\(^{-}\)Ar spectrum by direct comparison to the spectra computed for the I–III monomers is justified by the minor impact of successive Ar solvation on the appearance of the Ama\(^{-}\)Ar spectrum. Hence, the IRPD spectra suggest that the weak interaction with Ar causes only a small but noticeable perturbation on both the structure and IR spectra of I–III. This perturbation is most pronounced for the \(\nu_{\text{NH}}\) frequencies, which indicates that the NH group with its acidic and highly charged NH protons are the most attractive binding sites for Ar (and also other neutral ligands). To this end, we have calculated a large variety of Ama\(^{-}\)Ar\(_n\) isomers for each core isomer (7–13), and their structures, binding energies, IR spectra, and charge distributions are given in Supporting Information. For all considered I–Ar, II–Ar, and III–Ar isomers, the effect of Ar complexation is less than 9 \(\text{kJ mol}^{-1}\) (I), 5 \(\text{kJ mol}^{-1}\) (II), and 3 \(\text{kJ mol}^{-1}\) (III) for the most sensitive \(\nu_{\text{NH}}\) and \(\nu_{\beta_{\text{Ar}}H}\) modes. Similar small effects are predicted for the clusters with two and three Ar ligands. The Ar ligands are bound via weak dispersion and induction forces to the acidic NH group and/or the C\(_{\text{Ar}}\)H\(_{\text{Ar}}\) moiety with total binding energies of \(D_{\text{B}}=4.1–8.9 \text{kJ mol}^{-1}\) \((n=1)\), \(11.2–18.2 \text{kJ mol}^{-1}\) \((n=2)\), and \(19.8–27.4 \text{kJ mol}^{-1}\) \((n=3)\). The energy differences between individual Ama\(^{-}\)Ar isomers are small and less than \(\Delta E_{\text{B}}=6 \text{kJ mol}^{-1}\) from the global minimum, so that it is difficult to exclude any of them. Hence, we will discuss these briefly only the global minima of Ama\(^{-}\)Ar\(_n\). The only experimental information about the binding energies of Ama\(^{-}\)Ar\(_n\) comes from the observation that single-photon IRPD is sufficient to evaporate all three Ar ligands of Ama\(^{-}\)Ar, in the XH stretch range \((>2800 \text{ cm}^{-1})\), providing an upper limit for the average Ar binding energy of the order of 1000 \text{ cm}^{-1} \((12 \text{ kJ mol}^{-1})\), which is fully consistent with the computed Ar binding energies.

The preferred binding site of the first Ar ligand in the most stable I–Ar(I), II–Ar(I), and III–Ar(I) global minima for each isomer I–III is in all cases the NH\(_2\) group (Figure 1). However, due to substantial charge delocalization into the C\(_{\text{Ar}}\)H\(_{\text{Ar}}\) moiety, the NH…Ar H-bonds are rather weak \((R_{\text{NH…Ar}}=2.64–2.75 \text{ Å})\) and substantially supported by additional van-der-Waals type contacts to the adjacent CH\(_2\)/CH\(_3\) groups \((R_{\text{CH…Ar}}=2.97–3.17 \text{ Å})\). As a result, the NH…Ar H-bonds are strongly nonlinear \((\phi_{\text{NHAr}}=142.9–152.7^\circ)\), with binding energies of \(D_{\text{B}}=8.4–8.9 \text{kJ mol}^{-1}\). Upon Ar attachment, the N–H proton donor bonds are slightly elongated (by 1 \text{ Å}) with small red-shifts in the \(\nu_{\text{NH2}}\) modes (<9 cm\(^{-1}\), while the involved C–H bonds slightly contract (up to 1 \text{ Å}) resulting in minor blue-shifts in the corresponding \(\nu_{\text{CH2}}\) modes (<7 cm\(^{-1}\)). The charge transfer from Ama\(^{-}\) to Ar is also small (6–7 me) upon complexation, and most other bonds are nearly unaffected. The I–Ar(II) isomer with a nearly linear NH…Ar bond but no CH…Ar contact is only slightly higher in energy \((\Delta E_{\text{B}}=0.7 \text{kJ mol}^{-1}\), \(D_{\text{B}}=7.7 \text{kJ mol}^{-1}\), \(R_{\text{NH…Ar}}=2.59 \text{ Å}\), \(\phi_{\text{NHAr}}=167.9^\circ\), Figure S16) indicating the subtle competition between the weak NH…Ar H-bonds and the CH…Ar van-der-Waals contacts in these clusters. Nonetheless, also for this stronger NH…Ar H-bond, the perturbation of the NH\(_2\) group is still minor \((\Delta E_{\text{NH2}}=1 \text{ Å})\). The other less stable Ar binding motifs in I–Ar(III–VIII), II–Ar(II–VII), and III–Ar(VII) are mainly weak van-der-Waals contacts to the C\(_{\text{Ar}}\)H\(_{\text{Ar}}\) moiety further away from the NH\(_2\) group, with binding energies of \(D_{\text{B}}=4.1–8.0 \text{kJ mol}^{-1}\), which have even less impact on the monomer structures than isomers with Ar binding to the NH\(_2\) group.

The preferred binding site of the second Ar ligand in the most stable I–Ar(I), II–Ar(I), and III–Ar(I) minima is the mirror image position of the first Ar ligand, thereby restoring C\(_2\) symmetry again (Figure 5). The total binding energies of \(D_{\text{B}}=16.9–18.2 \text{kJ mol}^{-1}\) are essentially twice that of the corresponding (I–III–Ar(I)) dimers, due the equivalent binding sites offered by the two NH proton donor sites of the NH\(_2\) group. Apparently, nonadditive three-body contributions to the intermolecular interactions are very minor. Consequently, the properties of the two nonlinear intermolecular NH…Ar bonds and CH…Ar contacts \(\theta_{\text{NH…Ar}}=2.63–2.74 \text{ Å}\), \(\phi_{\text{NHAr}}=143.1^\circ–153.3^\circ\), \(R_{\text{CH…Ar}}=2.98–3.20 \text{ Å}\) are similar to those of the (I–III–Ar(I)) minima with one Ar ligand. The total charge transfer to the ligands \((\Delta q=12–14 \text{ me})\) increases also linearly with the number of Ar atoms. Overall, the effects on the monomer structures and IR spectra are rather minor also for attaching the second Ar ligand. For all considered Ama\(^{-}\)Ar\(_n\) isomers, I–Ar(I–VIII), II–Ar(I–IX), and III–Ar(I–X), the total frequency shifts of the \(\nu_{\text{NH2}}\) modes are below 6, 10, and 3 cm\(^{-1}\), respectively.

In the most stable I–Ar(I), II–Ar(I), and III–Ar(I) isomers, the three ligands are arranged around the NH\(_2\) group such that the first two Ar atoms form nonlinear NH…Ar H-bonds with similar binding properties \((R_{\text{NH…Ar}}=2.62–2.64 \text{ Å}, \phi_{\text{NHAr}}=144.2–161.0^\circ)\), \(R_{\text{CH…Ar}}=2.93–3.16 \text{ Å}\) as in (I–III–Ar(I)), while the third ligand is attached directly to the N atom at \(R_{\text{Ar–N}}=3.36–3.38 \text{ Å}\) (Figure 5). The N atom also carries substantial positive charge due to electron removal from the N lone pair upon ionization (either a 2\(p_x\) orbital of N in I or a 2\(p_x\) orbital of the C–N group in II/III).

The total binding energies of \(D_{\text{B}}=27.4–27.7 \text{kJ mol}^{-1}\) are some-
what less than three times those of (I–III)-Ar(I), because the N site is less attractive than the two NH sites. As a result of the weaker third intermolecular bond, the total charge transfer to the ligands increases only slightly ($\Delta q = 15, 18, 19 \text{me}$). Also the third Ar ligand has a vanishingly small impact on the monomer structures and their vibrational modes ($\Delta \nu_{\text{NH}} < 6, 10, \text{and } 3 \text{ cm}^{-1}$ for I–III).

As expected, comparison of the IRPD spectra of Ama$^+\cdot\text{Ar}_{1-3}$ with the calculated IR spectra of the various cluster isomers yields the same assignment (Table S3) as the comparison with the spectra computed for the monomers I–III because of the weak Ama$^+\ldots\text{Ar}$ interaction. Significantly, the effects of Ar on the $\nu_{\text{NH}}$ modes is much smaller than the splitting observed in the experimental IRPD spectra arising from different isomers, indicating that the bands $J_{1-3}$ and $K_{1-3}$ do not arise from three distinct Ar binding sites of a single Ama$^+$ isomer but from three different Ama$^+$ isomers. Specifically, all frequencies of the calculated modes of the most stable (I–III)-Ar(I) isomers differ from those of the I–III monomers by less than $4 \text{ cm}^{-1}$ in the fingerprint range, $9 \text{ cm}^{-1}$ in the $\nu_{\text{CH}}$ range, and $5 \text{ cm}^{-1}$ in the $\nu_{\text{NH}}$ stretch range. Anharmonic calculations confirm the given assignment and show very good correspondence between bands H and I ($3151$ and $3267 \text{ cm}^{-1}$) with $2\nu_{\text{NH}}$ of I-Ar(I) and III-Ar(I) ($3150$ and $3254 \text{ cm}^{-1}$), respectively. Significantly, band I cannot be assigned to a $\nu_{\text{NH}}$ fundamental which is red-shifted by Ar-tagging but must be explained by an $2\nu_{\text{NH}}$ overtone band because of its blue-shift upon sequential Ar solvation and when going from Ar to $\text{N}_2$. In summary, the IRPD spectra of Ama$^+\cdot\text{Ar}_{1-3}$ show the clear signature of at least three different monomers in the $\nu_{\text{NH}}$ range and provide a very good approximation of the IR absorption spectrum of bare Ama$^+$.

Overall, the largest complexation shifts in the IRPD spectra of Ama$^+\cdot\text{Ar}_n$ occur for $n = 1$ and 2, and this result is confirmed by the calculations with the two H-bonded Ar ligands for $n = 2$. As expected, the less strongly N-bonded third Ar ligand has less impact on both the measured and computed IR spectra.

**Ama$^+\cdot\text{N}_2$ dimer**

Unlike Ar ligands, attachment of $\text{N}_2$ has a stronger effect on the monomer structures due to its larger proton affinity (PA$=494$ vs. $369 \text{kJ mol}^{-1}$) and additional quadrupole moment.[33] Because of the anisotropy of the charge-quadrupole and charge-induced dipole interaction, $\text{N}_2$ ligands approach a positive charge in a linear configuration.[25a,c,32] Due to the higher proton affinity, the

---
trend of N₂ to form nearly linear NH…N₂ H-bonds to the NH₂ group is much more pronounced than for Ar. As a consequence, these H-bonded isomers are the global minima on the (I–III)-N₂ potentials, with \( D_\text{g} = 13.4, 15.7, \text{and} \ 13.9 \, \text{kJ mol}^{-1} \) for (I–III)-N₂(I). These are substantially more stable than those isomers in which N₂ simply binds to the C₆H₄ moieties, with \( D_\text{g} = 6.6–9.3, 8.4–10.1, \text{and} \ 7.0-9.8 \, \text{kJ mol}^{-1} \) for I-N₂(II–V), II-N₂(II–V), and III-N₂(II–VII), respectively. Thus, the H-bonded global minima are well separated from the van-der-Waals local minima, with energy gaps of \( \Delta E = 4.1, 5.6, \text{and} \ 4.1 \, \text{kJ mol}^{-1} \) for I–III, respectively. To this end, we discuss here only the most stable minima (I–III)-N₂(I) (Figure 1) and their IR spectra are compared in Figure 6 to the measured IRPD spectrum (Table S4).

Compared to Ar, N₂ is bound to the NH₂ group via stronger and more linear intermolecular H-bonds (\( R_{\text{NH-N₂}} = 2.162, 2.144, \text{and} \ 2.144 \, \text{Å} \) and \( \phi_{\text{new}} = 179.1°, 178.3°, \text{and} \ 170.5° \) for I–III) and larger charge transfer to the ligand (\( \Delta q = 14, 14, \text{and} \ 11 \, \text{me} \)). The partial charge on the NH proton donor atoms is increased (by 12, 10, and 9 cm⁻¹) calculated at the B3LYP level. The NH…N₂ interaction produces bands that are blueshifted by a factor of 2–3, an effect typical for H-bonds. Thus, the H-bonded global minima are well reproduced by the measured blue-shifts of the 2ν_{NH} overtones of isomers I and III, assigned to bands H (+21 cm⁻¹) and I (+15 cm⁻¹). As the ν_{NH} modes are nearly identical to the corresponding monomer modes, peaks A–G of the N₂ spectrum can be identified analogous to the Ar spectrum.

Figure 6. IRPD spectrum of Ama⁻+H₂O in the XH stretch range compared to linear IR absorption spectra of (I–III)-N₂(I) calculated at the B3LYP-D3/cc-pVTZ level. The positions of the transition observed and their vibrational and isomer assignment are listed in Table S4. Relative energies (\( E_0 \)) are given in kJ mol⁻¹.

Ama⁺+H₂O dimer

The interaction between Ama⁺ and H₂O is much stronger than with Ar and N₂, because H₂O has a much larger proton affinity (PA = 691 kJ mol⁻¹) and an additional large dipole moment, giving rise to strong electrostatic cation-dipole attraction. Again, H₂O prefers binding to the acidic NH₂ group rather than to the C₆H₄ moieties, which has already been reported for the cage isomer I in our previous study of microhydrated Ama⁺(H₂O)₃ clusters. Binding of H₂O to isomers II and III is reported here for the first time and compared with new experimental IRPD data (Figure 7). Calculated energies of all considered Ama⁺+H₂O isomers are listed in Table S12 and their IR spectra are shown in Figure S31–S33. All isomers have a favorable charge-dipole configuration with the electronegative O atom of H₂O pointing toward the positive charge of I–III. Like for N₂, the binding energies of the H-bonded global minima, \( D_\text{g} = 61.4, 66.4, \text{and} \ 58.7 \, \text{kJ mol}^{-1} \) for (I–III)-H₂O(I), are much higher than those with H₂O attached to the C₆H₄ moiety, \( D_\text{g} = 33.6, 42.0, \text{and} \ 39.1 \, \text{kJ mol}^{-1} \) for (I–III)-H₂O(II), leading to large energy gaps between NH-bonded and CH-bonded isomers (\( \Delta E = 27.8, 24.4, \text{and} \ 19.5 \, \text{kJ mol}^{-1} \) for I–III). Hence, we discuss only the (I–III)-H₂O(I) global minima with the strong NH…O ionic H-bonds further (Figure 1), and their IR spectra are compared in Figure 7 to the measured IRPD spectrum (Table S5).

In all (I–III)-H₂O(I) global minima, H₂O forms a nearly linear and very strong and short NH…O ionic H-bond to the NH₂ group (\( R_{\text{NH-O}} = 1.77, 1.77, \text{and} \ 1.82 \, \text{Å} \) and \( \phi_{\text{new}} = 170.5°, 171.6°, \text{and} \ 169.7° \) for I–III). As a result of the very strong H-bonds, the ν_{NH} normal modes of the NH₂ group of the monomers decouple into free and bound NH stretch modes (\( \nu_{\text{NH}}^{\text{free}} \)) upon monohydration. The N–H proton donor bonds of I and II are substantially elongated (\( \Delta R_{\text{NH}} = 21 \text{ and } 20 \, \text{mÅ} \)) leading to
massive red-shifts in the $ν_H^b$ frequencies down to 3023 and 3033 cm$^{-1}$, along with drastic enhancements in the IR intensities (factor 6 and 8 compared to $ν_H^a$). The N–H bond of III is less stretched than in I and II ($Δν_H^b=16$ mÅ), leading to a smaller red-shift down to $ν_H^b=3123$ cm$^{-1}$ with an intensity increase of factor 5. The free N–H bonds hardly change, resulting in less intense free $ν_H^a$ modes at 3378, 3389, and 3420 cm$^{-1}$ for I–III. Charge transfer to H$_2$O is significantly higher than for N$_2$ and Ar ($Δν=38, 41, 33$ me). However, due to the low ionization energy of Ama (IE = 8.6 vs. 12.6 eV)\cite{33a} and its open-cage isomers, and the higher proton affinity of the amantadyl radical and its open-cage isomers (PA = 960, 980, 1010 kJ mol$^{-1}$ for removing H$^+$ from the NH$_2$ group) as compared to H$_2$O (PA = 691 kJ mol$^{-1}$)\cite{33b} the positive charge remains mostly on the C$_8$H$_4$NH$_2$ moiety and no proton transfer to H$_2$O occurs upon monohydration. As already noted previously, H$_2$O attachment to I has a significant impact also on the structure of the adamantyl cage.\cite{24} For example, the C–N bond is slightly elongated by 8 mÅ and the C1–C3 bond contracts by 39 mÅ. As a result, the lowest $ν_{OH}$ mode is blue-shifted by 29 cm$^{-1}$ to 2869 cm$^{-1}$, while the other $ν_{CH/CH_2}$ frequencies do not change much. The impact of H$_2$O on structure II is much smaller. The C–N double bond contracts by 4 mÅ and the C1...C3 distance of the broken bond shortens by 10 mÅ. The $ν_{CH}$ mode is only slightly red-shifted to 2814 cm$^{-1}$, and the remaining $ν_{CH/CH_2}$ frequencies hardly change. H$_2$O attachment to III results in a contraction of the C–N double bond by 8 mÅ and a larger increase in the C1...C3 distance by 51 mÅ, but again the $ν_{CH/CH_2}$ frequencies change only slightly.

As discussed previously, comparison of the IRPD spectrum of Ama$^+$H$_2$O with the spectrum predicted for I-H$_2$O(I) demonstrates that all major bands in the experimental spectrum can be explained by this isomer.\cite{24} Briefly, the red-shifted $ν_{OH}^{b}$ mode (3023 cm$^{-1}$) and free $ν_{OH}^{a}$ mode (3378 cm$^{-1}$) of I-H$_2$O(I) are clearly observed at 2990 (L$_1$) and 3368 cm$^{-1}$ (M$_3$). Band B at 2865 cm$^{-1}$ is assigned to $ν_{OH}^a$ (2869 cm$^{-1}$) and band D at 2937 cm$^{-1}$ to $ν_{OH}^b$ modes (2919 and 2957 cm$^{-1}$). Peaks N and O at 3627 and 3717 cm$^{-1}$ in the free OH stretch range are readily assigned to $ν_{OH}^{a}$ (3597 cm$^{-1}$) and $ν_{OH}^{b}$ (3682 cm$^{-1}$) of I-H$_2$O(I). The bands H and V at 3187 and 3213 cm$^{-1}$ are probably arising from $2β_{OH}$ and $2β_{OH}$ overtones of I-H$_2$O(I) predicted at 3176 and 3238 cm$^{-1}$. An anharmonic calculation supports this assignment with calculated frequencies of 3187 and 3211 cm$^{-1}$, respectively.

For the remaining bands in the Ama$^+$H$_2$O spectrum two scenarios emerge. In scenario I, all bands are assigned to H$_2$O clusters of isomer I. Then, bands I (3318 cm$^{-1}$), M$_3$ (3387 cm$^{-1}$), and M$_5$ (3433 cm$^{-1}$) may be assigned to the free $ν_{OH}$ modes of I-H$_2$O isomers with a completely free NH$_2$ group, such as I-H$_2$O(I) and I-H$_2$O(II) with $ν_{OH}^a=3329$ and 3326 cm$^{-1}$ and $ν_{OH}^b=3445$ and 3326 cm$^{-1}$, respectively (Figure S31). Assuming that only the two most stable isomers I-H$_2$O(I) and I-H$_2$O(II) are present, one can roughly estimate their population ratio as 10:1 from the integrated peak intensities of peaks M$_3$ and I and the calculated IR cross sections, and assuming similar dissociation efficiencies for H$_2$O elimination. Although we cannot exclude scenario I, we consider it unlikely because of the high relative energy gap between I-H$_2$O(I) and I-H$_2$O(II)(III) of 27.8 and 30.9 kJ mol$^{-1}$, and the clear detection of the open-cage isomers II and III in the IRPD spectra of Ama$^+$Ar$_{1,2}$ and Ama$^+$N$_2$.

Following our favored scenario II, we attribute bands L$_3$ and M$_5$ at 3021 and 3387 cm$^{-1}$ to $ν_{OH}^b$ and $ν_{OH}^a$ of II-H$_2$O(I) predicted at 3033 and 3389 cm$^{-1}$. Moreover, the broad and less intense features L$_3$ and M$_5$ at 3147 and 3433 cm$^{-1}$ are indicative of a small population of III-H$_2$O(I), with computed values of $ν_{OH}^a=3132$ cm$^{-1}$ and $ν_{OH}^b=3420$ cm$^{-1}$. The population of II-H$_2$O(I) and III-H$_2$O(I) can then be roughly estimated as ~30% and ~10% of I-H$_2$O(I) by considering the calculated and observed IR intensities of peaks M$_3$, I. The overall population ratio for I–III of 10:3:1 for the H$_2$O-tagged cations may be compared to that derived for the Ar-tagged cations (10:3:7), indicating similar relative abundance for II but a rather reduced population for III, a conclusion rationalized below by considering the potential energy diagram for ring opening and 1,2 H-shift. In scenario II, the bands B, D, N, and O mostly assigned to I-H$_2$O(III) will also contain contributions from the corresponding modes of II/III-H$_2$O(I). Compared to Ar and N$_2$, bands H (3187 cm$^{-1}$) and I (3318 cm$^{-1}$) of the H$_2$O spectrum are shifted further to the blue, coherent with their assignment to $2β_{OH}$ of I-H$_2$O(I) and I-H$_2$O(III), respectively. Finally, band V (3213 cm$^{-1}$) can be assigned to $2β_{OH}$ of (I–III)-H$_2$O(I) predicted at 3238, 3204 and...
3203 cm\(^{-1}\), which explains why this peak \(V\) is observed only in the \(\text{Ama}^+\text{H}_2\text{O}\) spectrum.

The computed binding energies of \(D_q \sim 60 \text{kJ mol}^{-1}\) (\(\sim 5000 \text{ cm}^{-1}\)) for the assigned \(\text{Ama}^+\text{H}_2\text{O}\) isomers substantially exceed the IR photon energy employed for single-photon IRPD (\(< 4000 \text{ cm}^{-1}\)). Consequently, the measured spectrum is produced by internally hot cluster ions that contain an internal energy of at least 1000 cm\(^{-1}\). As a result, the IRPD spectrum of \(\text{Ama}^+\text{H}_2\text{O}\) does not reflect the fundamental transitions (\(\nu\)) of cold clusters but sequence hot bands of the type \(\nu + \nu_r - \nu_w\), where \(\nu_r\) are low-frequency inter- and intramolecular modes. This effect causes the widths of the \(\text{Ama}^+\text{H}_2\text{O}\) transitions to be broader than those of \(\text{Ama}^+\text{Ar}_n\) and \(\text{Ama}^+\text{N}_2\) for which \(h\nu > D_q\) (Table 1, Figure 3).

**Comparison between \(\text{Ama}^+\text{L}\)**

In addition to the nascent cage isomer I of \(\text{Ama}^+\), the analysis of the IRPD spectra of \(\text{Ama}^+\text{Ar}_3\) by DFT calculations provides clear evidence for the formation of the open-cage structures II and III, when using an electron ionization energy of up to 200 eV. The presence of six peaks in the \(v_{\text{NH}}\) range (\(J_{1,0}, K_{1,0}\)) and three intense bands in the \(\rho_{\text{NH}_2}\) range (\(Q_{1,0}\)) clearly indicates the existence of (at least) three different monomer isomers. Moreover, I–III can also be assigned in the \(\text{Ama}^+\text{L}\) spectra with \(\text{L}=\text{N}_2\) and \(\text{H}_2\text{O}\). All three isomers differ strongly by the structural and vibrational properties of their \(\text{NH}_2\) groups, which may serve as sensitive probe of their structure. The B3LYP–D3 calculations identify I as the canonical cage radical cation, while II and III are bicyclic distonic iminium ions. The IRPD spectra clearly indicate that the \(\text{NH}_2\) group is preserved in all three isomers upon ionization and structural rearrangements. This acidic and partially positively charged \(\text{NH}_2\) group is in all three isomers the preferred binding site for neutral ligands, while the \(\text{C}_9\text{H}_{15}\) moiety is less attractive. The preferred cluster growth is thus solvation of the \(\text{NH}_2\) group by formation of one or two \(\text{NH}...\text{L}\) H-bonds. For \(\text{L}=\text{Ar}\), these H-bonds are very weak and rather nonlinear because they compete with weak CH...L van-der-Waals contacts to the \(\text{C}_9\text{H}_{15}\) moiety. In contrast, the \(\text{NH}...\text{N}\) and \(\text{NH}...\text{O}\) H-bonds are much stronger because of the additional electrostatic interactions arising from quadrupole and dipole moments of \(\text{N}_2\) and \(\text{H}_2\text{O}\), respectively. As a result, these H-bonds are rather linear, with no or little interaction of \(\text{L}\) with \(\text{C}_9\text{H}_{15}\) unit. For example, the interaction strength in I–L increases in the order \(\text{Ar} < \text{N}_2 < \text{H}_2\text{O}\) as \(D_q = 8.4 < 13.4 < 61.4 \text{kJ mol}^{-1}\), in line with the proton affinity of the ligands (PA = 369 < 494 < 691 KJ mol\(^{-1}\)). As a result, the intermolecular \(\text{NH}...\text{L}\) bonds get shorter (2.72 > 2.14 > 1.77 Å) and charge transfer from I to L increases (6 < 14 < 38 me). Because of the stronger intermolecular bond, the perturbation on the \(\text{NH}_2\) group gets stronger, with larger \(N\)–\(H\) bond elongations (\(\Delta\sigma_{\text{NH}} = 1 < 4 < 21 \text{ mÅ}\)), and the proton donor \(\text{NH}\) stretch frequency experiences increasing red-shifts down to 3222, 3276, and 3023 cm\(^{-1}\). In general, the interaction of \(\text{L}\) with \(\text{I}\) is slightly stronger than with I and III for all three ligands (\(D_q = 8.4 < 8.9 < 8.8, 13.4 < 15.7 < 13.9, 61.4 < 66.4 < 58.7 \text{kJ mol}^{-1}\) for \(\text{Ar, N}_2, \text{H}_2\text{O}\)), but overall the variation of the ligand binding affinities is small. This is fully consistent with the charge on the acidic NH protons (\(q_{\text{NH}} = 0.405 < 0.421 < 0.411\)) and the \(\text{NH}...\text{L}\) bond lengths.

Figure 8 compares the computed and experimental \(\text{NH}\) stretch frequencies for all investigated \(\text{Ama}^+\text{L}\) clusters and the overall good qualitative and quantitative agreement supports the given vibrational and isomer assignments. When compared to other NH...L ionic H-bonds, such as those in clusters of small ions (e.g., \(\text{NH}_3^+, \text{N}_2\text{H}_4^+\)) or aromatic amines (e.g., anilines, protonated pyrimidines)\(^{[25,26]}\), the \(\text{NH}...\text{L}\) bonds in (I–III)L are significantly weaker and less directional, mainly due to the lower acidity of the \(\text{NH}_2\) group resulting from the large charge delocalization into the \(\text{C}_9\text{H}_{15}\) moiety and the high PA of the \(\text{C}_9\text{H}_{15}\text{NH}\) radicals.

**Potential energy profile for cage opening in \(\text{Ama}^+\) and \(\text{Ama}^+\text{L}\)**

In the following, we discuss the process of ionization, cage-opening reaction, subsequent 1,2 H-shift, the corresponding potential energy surface and its dependence on the solvent. Neutral \(\text{Ama}\) is ionized in the high-pressure region of the supersonic plasma expansion of the EI source by electron and/or chemical ionization. To this end, electrons hit the expansion gas with a kinetic energy of up to 200 eV, leading to a variety of processes including elastic and inelastic scattering, where the electrons may lose kinetic energy and also produce secondary electrons. At some point, direct EI of \(\text{Ama}\) (IE < 10 eV\(^{[16b]}\)) with primary or secondary electrons occurs, which may compete with EI or electronic excitation of carrier gas atoms and ligand molecules which may then ionize \(\text{Ama}\) in collisions by exothermic charge transfer and/or Penning ionization. When \(\text{Ama}\) is ionized by fast electrons, higher excited states may be populated, which decay very fast by

![Figure 8](image-url)

**Figure 8.** Experimental and calculated frequencies (in cm\(^{-1}\)) B3LYP-D3/cc-pVTZ of the \(v_{\text{NH}_2}^\text{I}\) and \(v_{\text{NH}_2}^\text{II}\) modes of I–III and (I–III)L with \(\text{L}=\text{Ar, N}_2, \text{H}_2\text{O}\) as a function of the proton affinity of the ligands.
internal conversion into the ground electronic state or fragment. Part of the produced nascent Ama⁺ population (isomer I will be initially produced due to vertical ionization processes) will then cool down by collisions in the expansion to form cold ions I. Some part has enough energy to overcome the barriers for cage opening and 1,2 H-shift and will then cool down to generate cold ions II and III. As a final step, the cold ions will form clusters by three-body aggregation. Cluster formation may also take place during the isomerization reaction and the cooling process. A further route, which is particularly feasible for H₂O, is the formation of larger neutral Ama(H₂O)ₖ clusters in the expansion, which are then ionized and cool down via collisions and/or ligand evaporation. For the latter pathway, it is also necessary to consider the potential of the clusters for the ionization-induced rearrangement reaction. To summarize, experimentally the energetics and kinetics of the processes occurring in the plasma expansion are not well defined.

The potential for the reaction of the monomer is shown in Figure 2. Briefly, Ama is vertically ionized by electron removal from the N lone pair (HOMO) to produce the radical cation I (Eₓ = 45.9 kJ mol⁻¹). As a result, the pyramidal NH₂ group becomes planar and due to increased delocalization of the N lone pair orbital, the C–N bond order increases from 1 to ~1.5, and the adjacent C1–C3 bond is slightly activated, which is the first step for opening the cage. The HOMO of I is delocalized over the whole cation (Figure S35), while most charge remains on the CNH₂ group (0.528 e). For highly energetic I, it is possible to overcome the barrier for breaking the C1–C3 bond and opening the cage via TS(I–II) (Vₛ = 54.1 kJ mol⁻¹, Eₓ = 100.0 kJ mol⁻¹), accompanied by a chair–boat conversion of the cyclohexane ring carrying the NH₂ group. This process results in a separation of charge and spin, so that the resulting shallow minimum II is a bicyclic distonic iminium ion (Eₓ = 87.4 kJ mol⁻¹), with most of the positive charge located on the CNH₂ group (0.754 e) and the spin located on the primary CH₃⁺ radical center at C3 (Eₓ = 1005). The HOMO of II is mostly the 2p orbital of the CH₃⁺ group with an sp² C atom (Figure S33). In the final 1,2 H-shift to the CH₃⁺ center, the much more stable tertiary CH₃⁺ radical center (Eₓ = 0.627) is formed via a barrier of Vₛ = 81.6 kJ mol⁻¹ (Eₓ = 169.0 kJ mol⁻¹), accompanied by a boat–chair back conversion of the cyclohexane ring, resulting in maximum stabilization of the radical in the distonic bicyclic iminium ion III (Eₓ = 0), which is by far the global minimum on the Ama⁺ potential. The HOMO of III is almost completely delocalized again over the entire cation, with some substantial orbital overlap between the 2p orbital of the C9 radical center and the 2px orbital of the C–N double bond (Figure S35). The partial charge of the CNH₂ group is reduced to 0.608 e, because some of the charge is transferred to the tertiary C9 atom, but it is still slightly higher than in the initial structure I (0.528 e).

As the Ar and N₂ binding energies are very small (< 16 kJ mol⁻¹) compared to the energies involved in the potential energy profile with respect to barriers and relative energies of minima (Figure S34), these ligands are considered to have negligible influence on reaction efficiencies and the final population of the isomers I–III. In particular, they do not change the energetic order of I–III. As the ligand binding energies are similar for each I–III isomer, the potential energy profile for the Ama+ Ar dimers are very similar to that of bare Ama⁺, and we may reliably estimate from the relative isomer population in these clusters directly the isomer abundances of the monomers I–III. The population ratio of 10:3:7 for I–III derived from the β₉₂₀ intensities of the Ama⁺Ar spectrum are fully consistent with the potential energy profile predicted for the Ama⁺ monomer. The high abundance of I is due to its initial preparation by vertical ionization and the high barrier required for isomerization toward II and III of 54.1 and 123.1 kJ mol⁻¹, respectively. Thus, it is likely that a substantial population of Ama⁺ is trapped in the deep initial well by rapid collisional cooling despite of its high relative energy. The minor population of II is attributed to its shallow potential well (12.6 kJ mol⁻¹), while the higher population of III is rationalized by its highest stability. In addition, tunneling of H through the short barrier between II and III may also enhance the population of III. As illustrated in Figure 2, the potential energy profile computed for Ama⁺H₂O differs strongly from that of Ama⁺ (and Ama⁺ Ar/N₂). While the relative energies of the I–III minima and TS(I–II) are similar, TS(II–III) is much higher for Ama⁺H₂O (Eₓ = 213 vs. 169 kJ mol⁻¹), which suppresses the formation of III. Indeed, comparison of the population ratio inferred from the Ama⁺H₂O spectrum (10:3:7 for I–III) compared to that derived from Ama⁺Ar (10:3:7) fully confirms this view.

Comparison to Ada⁺

It is instructive to compare the properties of Ama⁺ with those of Ada⁺ to extract the impact of H–NH₂ substitution on the ionization-triggered cage-opening reaction. To this end, we calculated the structures, energies, charge and spin distributions, HOMO orbitals, and IR spectra of the three Ada⁺ isomers I–III, along with the potential for the rearrangement reaction at the same computational level for direct comparison with Ama⁺ (Figure S4, S36–37). Our results for the Ada⁺ potential are consistent with previous calculations[19c] and the potential is compared in Figure 2 to the one of Ama⁺. As can be seen, while the energetic order of the isomers I–III is the same for both Ama⁺ and Ada⁺, their relative energies and reaction barriers change drastically. Significantly, substitution of H by the NH₂ group qualitatively changes the ionization process. While in Ada⁺, ionization occurs from a bonding CC O orbital completely delocalized over the whole C₁₂H₁₀⁺ cage,[19g] ionization of Ama⁺ occurs from the N lone pair of the NH₂ group, which is only partly delocalized into the cage. As a result, the ionization energy of Ama is largely reduced compared to that of Ada (exp: 8.6 vs. 9.25 eV, B3LYP–D3: 7.88 vs. 8.81 eV)[19b,c] Isomer I of Ada⁺ (Eₓ = 5.4 kJ mol⁻¹) undergoes Jahn-Teller distortion from T₃ to C₁₁, symmetry, which leads to an elongation of the three C–C bonds parallel to the C₁ axis and a substantial activation of the C–H bond lying on this axis. This very acidic C–H bond with its high positive charge (δₓ = 0.354 e) is an attractive proton donor for H-bonding with neutral ligands, such as He, Ar, N₂, and H₂O.[19c,20] Significantly, while the electron-donating NH₂ group
in isomer I of Ama– strongly activates the C1–C3 bond (r_{C1C3} = 1.697 Å), which eventually breaks, no such activation is observed for ionization of Ada– (r_{C1C3} = 1.511 Å). Hence, the barrier for breaking this bond is much higher for Ada– than for Ama– (V_0 = 156.7 vs. 54.1 kJ mol⁻¹), i.e., H—NH₂ substitution strongly facilitates cage opening. Similar to Ama–, isomer II of Ada– is located in a shallow potential well (9 vs. 13 kJ mol⁻¹) and thus much higher in relative energy (153.0 vs. 87.4 kJ mol⁻¹). It is also a-distonic ion with a CH₃⁺ radical group (s = 0.797) separated from the positive charge (Figure S11–S12), mostly located on the opposite CH₂—CH₂ moiety (δ_{CH} = 0.623 e). The energy barrier for the 1.2 H-shift at TS(II–III) is much lower compared to Ama– (V_0 = 37.8 vs. 81.6 kJ mol⁻¹) even though the relative energy to the global minimum III is higher (E₂ = 190.8 vs. 169.0 kJ mol⁻¹). Similar to III of Ama–, the HOMO of the global minimum III of Ada– is again delocalized over the entire cation (Figure S36). The charge of the CH₂—CH₂ group is reduced to 0.337 e, because a large amount of charge is now located at the tertiary radical C-atom (δ₂ = 0.410 e).

In summary, H—NH₂ substitution of Ada has a drastic impact on the potential for the cage-opening reaction and subsequent 1.2 H-shift. The barrier for this reaction is drastically reduced for Ama– and thus all three isomers I–III are detected in the IRPD spectra of Ama–L with L = Ar, N₂, and H₂O. In contrast, the high barrier for this process in Ada– explains why such a reaction was not detected in previous IRPD spectra of Ada– (with the same ligands). In previous work on Ada–L, cage opening was not considered but the comparison of the IR spectra computed for I–III of Ada– with the IRPD spectrum of Ada–H₂O in the CH stretch range (Figure S37) clearly demonstrates that the whole spectrum can be assigned to I, while the population of II and III are clearly below the detection limit, in accordance with the potential shown in Figure 2.

Concluding Remarks

In summary, the structural isomers of the Ama– cation and their solvated clusters with Ar, N₂, and H₂O are probed in a molecular beam by IRPD in the sensitive XH stretch and fingerprint ranges. The analysis of the IRPD spectra by DFT calculations provides direct evidence for the ionization-induced opening of the adamantyl cage followed by an 1,2 H-shift, and three distinct minima I–III are identified on the potential energy profile by the unique ν_{eq} and β_{eq} modes of their rather different NH₂ groups. Vertical electron ionization of Ama produces the canonical nascent cage isomer I of Ama–, which then via substantial barriers can react in a unimolecular reaction toward two distonic bicyclic iminium ions II and III. Significantly, isomer III with a tertiary radical center is the global minimum and thus more stable than the canonical cage structure I. In addition to the geometric and vibrational properties of the three isomers, details of the potential energy profile are revealed. The relative abundance of I–III are fully consistent with the shape of this potential energy profile, with respect to both the relative energies of the minima and the barriers for reaction. Although only a local minimum on the potential, the nascent isomer I is most abundant because it is directly produced by vertical ionization of the neutral cage molecule and largely trapped in its deep potential by collisional cooling. Part of the energetic population of I can overcome the high barriers toward II and III, whereby the well of II is quite shallow leading to its smallest population, while the substantial population of III is consistent with its highest stability. Tunneling of H through the short barrier between II and III may also enhance the population of III, a hypothesis which may be tested using partially deuterated samples in the future. Solvation of the ions with Ar and N₂ has little impact on the potential energy profile and isomer population, while the production of III is strongly suppressed for solvation with H₂O due to a large increase in the barrier for the II–III reaction. Comparison between Ama+ and Ada+ reveals that H—NH₂ substitution has a drastic impact on the geometric and electronic structure of the three isomers I–III due to the strong electron-donating character of the NH₂ group. The resulting orbital conjugation drastically reduces the barriers on the potential compared to Ada+; for which the much higher barriers have prevented the detection of the cage-opening reaction in previous related experiments. To test this hypothesis, experiments with cyanoadamantane are currently underway to study the effects of an electron-withdrawing substituent (CN) on the cage-opening potential energy profile. Significantly, the presented IRPD spectra of Ama–L₄ provide the first experimental evidence for the cage-opening and 1,2 H-shift reaction for any diamondoid cation and thus yield valuable insight into their chemical reactivity. As the radical cations of diamondoids are frequently invoked in the mechanism for (substitution) reactions in polar solvents, the results of the current study provide valuable insight for developing new routes in organic synthesis in diamondoid chemistry. In addition, the intermediates II and III may also be used in novel routes of iminium ion chemistry in solution, a strategy which has not been exploited so far. The acidic NH₂ group serves as the most attractive ligand binding site for all three ions I–III and the ligand- and size-dependent frequency shifts of the ν_{NH₂} and 2ν_{NH₂} modes provide a quantitative probe of the type and strength of the Ama–…L interaction and the sequence of the cluster growth. In general, the first two ligands form equivalent NH…L I–II–L as the two available NH protons before other less stable binding sites are occupied. In all cases, the interaction with II is stronger than with I and III which correlates with the acidity of the NH₂ group. For Ar ligands, the NH…Ar bonds are very weak and thus rather nonlinear because of competing CH…Ar contacts based on dispersion and induction forces. As a result, the Ama–Ar spectrum provides a very good approximation to the spectrum of bare Ama–. In contrast, stronger NH…N and NH…O I–II–L as the two available NH protons before other less stable binding sites are occupied. In all cases, the interaction with II is stronger than with I and III which correlates with the acidity of the NH₂ group. For Ar ligands, the NH…Ar bonds are very weak and thus rather nonlinear because of competing CH…Ar contacts based on dispersion and induction forces. As a result, the Ama–Ar spectrum provides a very good approximation to the spectrum of bare Ama–. In contrast, stronger NH…N and NH…O I–II–L as the two available NH protons before other less stable binding sites are occupied. In all cases, the interaction with II is stronger than with I and III which correlates with the acidity of the NH₂ group. For Ar ligands, the NH…Ar bonds are very weak and thus rather nonlinear because of competing CH…Ar contacts based on dispersion and induction forces. As a result, the Ama–Ar spectrum provides a very good approximation to the spectrum of bare Ama–. In contrast, stronger NH…N and NH…O I–II–L as the two available NH protons before other less stable binding sites are occupied.
