With the rapid diminution of fossil fuels the price of petroleum is soaring and the cost of a petroleum-based chemical industry continues to rise. Therefore, researchers are keen to find substitutes for fossil fuels. Biomass-derived carbohydrates, which are abundant, relatively inexpensive and renewable, are a promising alternative energy source and a renewable chemical feedstock.1–3 The conversion of carbohydrates into other useful products is now of great importance. Among those products, 5-hydroxymethylfurfural (HMF), which can be produced by the dehydration of fructose, is a potential intermediate used to synthesise bio-based fuels and chemicals.4–7

The dehydration of fructose into HMF can be carried out in methanol,8 water,9–13 organic solvents of high boiling point14–18 and ionic liquids.19–26 Some acidic catalysts are usually needed to assist the reaction. Liquid acids, although possessing moderate to excellent catalytic ability in fructose dehydration towards HMF in the aforementioned media,13,15,18,24 are highly corrosive and hard to separate from the reaction system, hindering their use in industrial manufacture.

Recent years witnessed frequent use of solid acids in converting fructose to HMF,11,16,27 for they are convenient to be handled and recycled with low corrosiveness to equipment. As with liquid acids, excellent catalytic activities have been demonstrated in several solid acid catalytic systems. For example, the solid acidic resin Amberlyst-15 was reported to be able to convert fructose into HMF with 100% yield in dimethyl sulfoxide (DMSO).16 However, the separation of HMF from DMSO requires significant energy input to evaporate DMSO.2 Moreover, the evaporation of the solvent will result in a highly concentrated HMF, which is unstable at high temperatures due to the undesired side reactions as described in Scheme 1.2 Dumesic and co-workers pointed out in their literature that at 343 K and 1.3 mbar, evaporating DMSO from 10 wt % HMF solution will lead to a 30% loss of HMF.2 Although more than 80% HMF yield can be achieved in 1-butyl-3-methylimidazolium chloride (BmimCl) catalysed by Amberlyst-15,27 the separation of HMF and the recycling of the ionic liquid are still two problems to be solved. The catalytic activities of most solid acids were found to be unsatisfactory in water with low HMF yields even at high reaction temperatures. For instance, Asghari and Yoshida used zirconium phosphate as catalyst to convert fructose into HMF at 513 K. However, only a 50% HMF yield was obtained.11

Solid acid-catalyzed conversion of fructose into furan derivatives, in organic solvents with low boiling point, has not been reported to date. In this paper, the catalytic activity of the solid acid Amberlyst-15 was further investigated in the conversion of fructose into 5-hydroxymethylfurfural (HMF) and 5-methoxymethylfurfural (MMF) in different low boiling solvent systems, catalysed by an acidic resin Amberlyst-15. The melted fructose can be converted into HMF on the surface of the solid resin catalyst in the presence of THF as an extracting phase, which is a good solvent for HMF and other by-products. The solid resin catalyst can be reused eleven times without losing its catalytic ability, with an average HMF yield of approximately 50%. Upon the addition of methanol, the generated HMF can further react with methanol to form MMF, and the total yield of HMF and MMF could be promoted to 65%.

GC–MS analysis confirms the formation of a small amount of methyl levulinate in methanol–organic solvent systems. The solid resin catalyst can be reused eleven times without losing its catalytic ability, with an average HMF yield of approximately 50%. Upon the addition of methanol, the generated HMF can further react with methanol to form MMF, and the total yield of HMF and MMF could be promoted to 65%.

Conversion of fructose into furan derivatives 5-hydroxymethylfurfural (HMF) and 5-methoxymethylfur-
fural (MMF) is performed in tetrahydrofuran (THF) and methanol–organic solvent systems, catalysed by
an acidic resin Amberlyst-15. The melted fructose can be converted into HMF on the surface of the solid
resin catalyst in the presence of THF as an extracting phase, which is a good solvent for HMF and other
by-products. The solid resin catalyst can be reused eleven times without losing its catalytic ability, with
an average HMF yield of approximately 50%. Upon the addition of methanol, the generated HMF can fur-
ter react with methanol to form MMF, and the total yield of HMF and MMF could be promoted to 65%.
GC–MS analysis confirms the formation of a small amount of methyl levulinate in methanol–organic
solvent system.

With the rapid diminution of fossil fuels the price of petroleum is soaring and the cost of a petroleum-based chemical industry continues to rise. Therefore, researchers are keen to find substitutes for fossil fuels. Biomass-derived carbohydrates, which are abundant, relatively inexpensive and renewable, are a promising alternative energy source and a renewable chemical feedstock.1–3 The conversion of carbohydrates into other useful products is now of great importance. Among those products, 5-hydroxymethylfurfural (HMF), which can be produced by the dehydration of fructose, is a potential intermediate used to synthesise bio-based fuels and chemicals.4–7

The dehydration of fructose into HMF can be carried out in methanol,8 water,9–13 organic solvents of high boiling point14–18 and ionic liquids.19–26 Some acidic catalysts are usually needed to assist the reaction. Liquid acids, although possessing moderate to excellent catalytic ability in fructose dehydration towards HMF in the aforementioned media,13,15,18,24 are highly corrosive and hard to separate from the reaction system, hindering their use in industrial manufacture.

Recent years witnessed frequent use of solid acids in converting fructose to HMF,11,16,27 for they are convenient to be handled and recycled with low corrosiveness to equipment. As with liquid acids, excellent catalytic activities have been demonstrated in several solid acid catalytic systems. For example, the solid acidic resin Amberlyst-15 was reported to be able to convert fructose into HMF with 100% yield in dimethyl sulfoxide (DMSO).16 However, the separation of HMF from DMSO requires significant energy input to evaporate DMSO.2 Moreover, the evaporation of the solvent will result in a highly concentrated HMF, which is unstable at high temperatures due to the undesired side reactions as described in Scheme 1.2 Dumesic and co-workers pointed out in their literature that at 343 K and 1.3 mbar, evaporating DMSO from 10 wt % HMF solution will lead to a 30% loss of HMF.2 Although more than 80% HMF yield can be achieved in 1-butyl-3-methylimidazolium chloride (BmimCl) catalysed by Amberlyst-15,27 the separation of HMF and the recycling of the ionic liquid are still two problems to be solved. The catalytic activities of most solid acids were found to be unsatisfactory in water with low HMF yields even at high reaction temperatures. For instance, Asghari and Yoshida used zirconium phosphate as catalyst to convert fructose into HMF at 513 K. However, only a 50% HMF yield was obtained.11

Solid acid-catalyzed conversion of fructose into furan derivatives, in organic solvents with low boiling point, has not been reported to date. In this paper, the catalytic activity of the solid acid Amberlyst-15 was further investigated in the conversion of fructose into 5-hydroxymethylfurfural (HMF) and 5-methoxymethylfurfural (MMF) in different low boiling point solvent. The advantages of solid catalyst together with the volatile solvents lie in not only low corrosiveness to equipment but also low energy consumption during the separation process.

When fructose was mixed with THF and Amberlyst-15 at 120 °C, it was found that the fructose was almost insoluble in...
THF. However, at such a high temperature, the fructose melted to yield a viscous liquid, which can then make good contact with the Amberlyst-15 and the dehydration of fructose took place. In addition to HMF, all the products are soluble in THF so that the products can be extracted into the THF phase in situ and the reaction proceeds smoothly. The THF layer could be recovered by simple decantation and then analysed using HPLC to determine the yield of HMF with the results shown in Table 1. It can be seen that as the amount of fructose decreased, both the fructose conversion and the HMF yield slightly increased, which might be ascribed to the poor thermal stability of fructose.28 The higher the fructose concentration in the reaction system, the more side reactions there are.

As illustrated in Table 1, entry 3, 0.29 g Amberlyst-15 was subsequently reused to investigate its stability towards catalyst recycling. For each run, 0.25 g fructose and 10 mL THF were added and the reaction proceeded at 120 °C for 20 min. After the THF layer was recovered, the solid acid Amberlyst-15 was dried in vacuum to remove the volatile component for the next cycle. 43.1–52.7% HMF yield could be achieved in each run. After recycling for eleven times, Amberlyst-15 still retained activity and the overall average yield of HMF was 48.3%. Although the HMF yield obtained in this way was much lower than that in DMSO or ionic liquids, it presented a new approach to synthesise HMF from fructose, which facilitated the separation of products with the solvent.

Methanol, a polar and inexpensive organic solvent with its boiling point of only 64.5 °C, is an excellent solvent in the preparation of HMF. Although the solubility of fructose in methanol at 25 °C was reported to be only 85 g/L,8 our visual observation demonstrated that 2 g fructose could be dissolved in 10 mL anhydrous methanol at 120 °C. In the presence of Amberlyst-15 as the catalyst, conversion of fructose into HMF occurred with the results shown in Table 2. As can be seen from the data in the table, just as the previously reported methanol–H2SO4 system,8 although a total yield of HMF and MMF could reach approximately 76% at 240 °C, its fructose concentration was as low as 10 g/L and the H2SO4 catalyst was highly corrosive at such a high temperature. The fructose content in this work is 200 g/L, which is considerably higher than that of methanol–H2SO4 system and is therefore more meaningful in process economy.

To further analyse the products produced during the fructose dehydration in methanol–THF solvents, the liquid phase of entry 6 in Table 2 recovered after reaction was dried in vacuum to remove the volatile components. The residue was then extracted with 80 mL diethyl ether three times. The combined ether layer was subsequently analysed using GC–MS with its gas chromatogram and the corresponding mass spectrum shown in Figure S1. It can be seen from Figures S1(a) that the diethyl ether phase consists of three main products. According to their corresponding mass spectra, they are determined to be HMF, MMF, and a small amount of methyl levulinate which is also regarded as a potential biofuel or fuel additive29 and might be the product of levulinic acid reacting with methanol. Assuming all the three components can be extracted into the diethyl ether phase, the yield of methyl levulinate by the areas of peak normalisation method was estimated to be around 4.8%.

Because the HMF yield increased dramatically in the methanol–THF solvent, the reactivity of fructose was further tested in methanol–acetone, methanol–ethyl acetate or methanol–chloroform and the results displayed in Table 3. When V\textsubscript{Methanol}/V\textsubscript{THF} = 2:8, a part of fructose was insoluble. Compared with the experimental results in Table 2, although the total yield of HMF and MMF in Table 3 was higher than that of the solely methanol system, it was still lower than that of methanol–THF system.

Table 1

| Entry | mm\textsubscript{fructose}/mm\textsubscript{Amberlyst-15} | Y\textsubscript{HMF} (%) | Conversion (%) |
|-------|------------------|------------------|------------------|

b The HMF yield and fructose conversion were determined by HPLC.
1. Experimental

1.1. Materials and experimental procedures

Fructose (≥99%) purchased from Solarbio Science & Technology Co., Ltd was used as a standard. 5-Hydroxymethylfurfural (≥99%) and 5-methoxymethylfurfural (≥98%) obtained from Wujiang YingChuang Chemical Reagent Co., Ltd were used as standards. Anhydrous MeOH (≥99.5%), acetone (≥99.5%) and chloroform were supplied by YingChuang Chemical Reagent Co., Ltd. Tetrahydrofuran (chromatographic grade) was obtained from SafeNet Tianjin Science and Technology Co., Ltd. Ethyl acetate (≥99.5%) and anhydrous diethyl ether were supplied by Tedia China Co., Ltd. Tetrahydrofuran (organic solvent) = 10 mL. 1: acetone; 2: ethyl acetate; 3: chloroform.

In a typical reaction, a certain amount of fructose, anhydrous MeOH, tetrahydrofuran and Amberlyst-15 were charged into a 150 mL autoclave vessel lined with Teflon. The vessel was then heated in an oil bath preset at 120 °C and then cooled down to room temperature. The liquid phase was decanted, diluted with water and then analysed using HPLC to determine the content of HMF and MMF.

1.2. Analytical methods

HMF and MMF were quantified using a Waters HPLC with an UV detector at 284 nm and a SunFire™ C18 column (4.8 × 150 mm) at 35 °C. The eluent whose flow rate was 0.6 mL/min was a mixture of MeOH and water with a MeOH to water volumetric ratio of 1:4. The amount of HMF and MMF was calculated using the external standard.

The fructose concentration was determined using a high-performance ion-exchange chromatograph with a pulsed amperometric detector (Dionex, ICS-3000) and a CarboPac™ PA10 carbohydrate column (4 × 250 mm) at 30 °C. The eluent was a 7.5 mM NaOH aqueous solution with a flow rate of 1.0 mL/min. The amount of fructose was calculated using the external standard.

GC–MS was performed using an Agilent 7890A gas chromatograph with a 5975C mass spectrometry detector. The temperature of the column (DB-5 ms, 50 m × 250 μm × 0.25 μm) was maintained at 50 °C for 3 min and then raised to 300 °C with a ramp rate of 15 °C/min for 5 min. The flow rate of Helium was 1 mL/min with the split ratio of 20:1.
