(Dated: June 24, 2021)

The production of entangled pairs of electrons in ferromagnet-superconductor-ferromagnet or normal metal-superconductor-normal metal three-terminal structures has aroused considerable interest in the last twenty years. In these studies, the distance between the contacts is limited by the zero-energy superconducting coherence length. Here, we demonstrate nonlocality and quantum correlations in voltage-biased three-terminal Josephson junctions over the ultra-long distance that exceeds the superconducting coherence length by orders of magnitude. The effect relies on the interplay between the time-periodic Floquet-Josephson dynamics, Cooper pair splitting and long-range coupling similar to the two-terminal Tomash effect. We find cross-over between the “Floquet-Andreev quartets” (if the spatial separation is smaller than the superconducting coherence length), and the “ultra-long-distance Floquet-Tomasch clusters of Cooper pairs” if the separation exceeds the superconducting coherence length, possibly reaching the same \( \sim 30 \mu m \) as in the Tomash experiments. The effect can be detected with DC-transport and zero-frequency quantum current-noise cross-correlation experiments, and it can be used for fundamental studies of superconducting quasiparticle quantum coherence in the circuits of quantum engineering.

I. INTRODUCTION

The recent developments in the field of quantum engineering allow manipulation of long-range quantum objects with a few degrees of freedom. Superconductivity is a platform for fundamental studies of large-scale quantum systems and for assembling quantum processors. Superconducting quasiparticles can generally propagate over the entire sample and quasiparticle poisoning turns out to severely limit the range of quantum mechanical coherence in superconductors. Superconducting devices with three or more terminals could naturally be used for fundamental studies of coherent quasiparticle propagation. Propagation over \( R_0 \) across one of the superconducting leads, say \( S_c \), trivially requires two interfaces, one with \( S_a \) and the other one with \( S_b \), thus forming \( S_a-S_c-S_b \) double Josephson junction where \( S_a \) and \( S_b \) are laterally connected to \( S_c \) at distance \( R_0 \). The field of multiterminal Josephson junctions has recently been enriched with the discovery of nontrivial topology and topology in the time-periodic Floquet dynamics.

In view of these recent contributions, we address here the fundamental question of the range of nonlocality and quantum correlations in the three-terminal devices formed with the two Josephson junction oscillators \( S_a-S \) and \( S_b-S \), sharing the grounded \( S_c \). In spite of the well-known classical synchronization of macroscopic Josephson junction circuits, the present paper surprisingly demonstrates mesoscopic quantum correlations in three-terminal Josephson junctions at the “ultra-long-distance” that exceeds the superconducting coherence length \( \xi_{ball}(0) \) by orders of magnitude.

Specifically, we consider a \( S_a \)-dot-\( S_c \)-dot-\( S_b \) three-terminal Josephson junction made with the BCS superconductors \( S_a \), \( S_b \) and \( S_c \) and two quantum dots (see figures 1a, 1b and 1c). This physical system has the following features: (i) The time-periodic Floquet-Josephson dynamics with single characteristic frequency if biasing is at commensurate voltage (18, 23); (ii) The nonlocal electron-hole or hole-electron conversions, i.e. Cooper pair splitting (24); (iii) The long-range quasiparticle propagation above the gap between the two remote quantum dots separated by the distance \( R_0 \). Then, we demonstrate that (i), (ii) and (iii) automatically imply long-scale quantum-mechanical clusters of Cooper pairs between the constituting \( S \)-dot-\( S \) junctions, even if the distance \( R_0 \) between them is much larger than the zero-energy superconducting coherence length \( \xi_{ball}(0) \), i.e. if \( R_0 \gg \xi_{ball}(0) \). These clusters can be viewed as being “the elementary quantum particles” that are exchanged between the two Floquet-Josephson junctions in a three-terminal configuration. Figure 1i features real-space representation of the lowest-order four-Cooper pair cluster corresponding to the “ultra-long-distance Floquet-Tomasch octets”.

In the absence of bias voltage, all superconducting leads are grounded and the three-terminal \( S_a-S_c-S_b \) Josephson junction (14, 23, 24) can be phase-biased with appropriate superconducting loops. The Andreev bound states are then coupled by the overlapping evanescent Bogoliubov-de Gennes wave-functions at a double interface, forming “Andreev molecules” with avoided crossings in their spectra, see Refs. 23 and 24. At equilibrium, nonlocality is limited by the superconducting coherence length \( \xi_{ball}(0) \) as a function of the distance \( R_0 \) between the \( S_a-S_c \) and \( S_c-S_b \) interfaces.

We note that a DC-Josephson-like resonance appears if the three superconducting terminals \( (S_a, S_c, S_b) \) are biased on the “quartet line” (14):

\[ (V_a, V_c, V_b) = (V, 0, -V). \]  (1)

The resulting Josephson relations \( \phi_a(t) = \phi_a + 2eVt/h \), \( \phi_b(t) = \phi_b - 2eVt/h \) and \( \phi_c(t) = \phi_c \) for the superconducting phase variables at time \( t \) imply the static “quartet phase variable” \( \phi_q(t) = \phi_a(t) + \phi_b(t) - 2\phi_c(t) = \phi_a + \phi_b - 2\phi_c \). This yields the quartet current-phase relation \( I_{c,q} \sin \phi_q \) in the limit of low values of the contact transparencies. The three recent experiments of the Grenoble (30), Weizmann Institute (31) and Harvard (32) groups show all signs of compatibility with the theory of the quartets, in addition to other experiments on multiterminal Josephson junctions. The reason why some experiments report the quartets while others do not is maybe a complex matter of the materials and geometry.
The present paper focuses on the range of the quartets at finite bias voltage $V$ being a fraction of the superconducting gap $\Delta$. Concerning propagation across $S_{i}$ between the two Josephson junctions, the Tomasz effect was experimentally shown in Refs. [59-91] to produce oscillations in the density of states of the superconducting quasiparticles in a two-terminal configuration, as a result of the finite superconducting film thickness reaching 33.2 $\mu$m in the experimental Ref. [91]. The “Tomasch effect” and the model proposed by McMillan and Anderson [80] provide sensitivity on the thin film boundary conditions, corresponding to the two-terminal nonlocal density-phase response, see also the contribution of Wolfram and Lehman [81]. The here considered three-terminal “Floquet-Tomasch effect for the Cooper pair clusters” couples one junction to the phase drop at the other junction according to the nonlocal current-phase response and it does not involve the same microscopic quantum process as the three-terminal density of state oscillations. The former is DC-current current response and the latter corresponds to AC-density oscillations. Nonlocality and quantum correlations are obtained in the Floquet-Tomasch effect over the ultralong-distance $R_{0} \gg \xi_{ball}(0)$ that is orders of magnitude larger than at equilibrium.

This ultralong-distance effect contrasts with the $F_{\alpha}SF_{b}$ ferromagnet-superconductor-ferromagnet and the $N_{\alpha}SN_{b}$ normal metal-superconductor-normal metal beam splitters, where nonlocality and quantum correlations are limited by the superconducting coherence length $\xi_{ball}(0)$, see for instance Refs. [54-77].

The paper is organized as follows. The physical picture is presented in section II. The model and methods are presented in section III. Analytical model calculations are presented in section IV. Section V deals with presentation of the numerical results. Perspectives on noise measurements are discussed in section VI. Summary of the paper is provided in section VII.

II. PHYSICAL PICTURE

We first present the basics of Cooper pair splitting and nonlocality limited by the superconducting coherence length, see Refs. [54-77]. The range of Cooper pair splitting is introduced in section II A for three-terminal $F_{\alpha}SF_{b}$ and $N_{\alpha}SN_{b}$ devices. Next, we proceed further in section II B with the ultralong-distance Floquet-Tomasch effect in a three-terminal $S_{a}$-$D_{x}$-$S_{c}$-$D_{x}'$-$S_{b}$ Josephson junction, where $D_{x}$ and $D_{x}'$ denote the two quantum dots.

A. Nonlocality of Cooper pair splitting

This subsection introduces nonlocality and quantum correlations in a three-terminal $F_{\alpha}SF_{b}$ or $N_{\alpha}SN_{b}$ device, in connection with Cooper pair splitting, see Refs. [54-77].

Andreev reflection [78] at a normal metal-superconductor (NS) interface converts the supercurrent carried by Cooper pairs in $S$ into normal current in $N$. Namely, spin-up electron from $N$ is Andreev-reflected as a spin-down hole and a Cooper pair is transmitted into the condensate. The semiclassical trajectories of the incoming electron and outgoing hole are separated on the NS interface by less than the superconducting coherence length $\xi_{ball}(0)$, which is why Andreev reflection is nonlocal at the scale of the superconducting coherence length.

The experimental evidence [54-61] for the theoretical prediction of nonlocal Andreev reflection [52-77] involves three-terminal configurations, such as the above mentioned $F_{\alpha}SF_{b}$ or $N_{\alpha}SN_{b}$ devices.

Regarding the range of Cooper pair splitting in three-terminal $F_{\alpha}SF_{b}$ and $N_{\alpha}SN_{b}$ devices, the zero-energy supercon-
in the ballistic limit, where $v_F$ is the Fermi velocity. This "size of a Cooper pair" is energy/frequency-$\omega$-sensitive:

$$\xi_{ball}(\omega-i\eta) = \frac{\hbar v_F}{\sqrt{\Delta^2-(\omega-i\eta)^2}}$$

(3)

where $v_F$ is the Fermi velocity. Eq. (3) diverges as the energy $\omega$ goes to the superconducting gap $\Delta$, see also Ref. 94 for the nonlocal conductance $\mathcal{G}_{ab}=\partial I_{ab}/\partial V_b$ at arbitrary bias voltage $V_b$ with respect to the superconducting gap.

**B. Ultralong-distance Floquet-Tomasch effect**

The introduction of “the Feynman diagrams” in calculations of the light-matter interaction was not only useful to represent the quantum processes, but it also yielded considerable shortcuts in the calculation of those scattering amplitudes. Here, the diagrams yield intuitive explanations and simple physical pictures for the numerical results presented in section V. Those diagrams represent the time-evolution of the quantum processes, but it also yielded considerable shortcuts in the calculation of those scattering amplitudes.

This subsection considers nonlocality in the $S_a-D_x-S_c-D_y-S_b$ three-terminal Josephson junction on figures $\text{[4]}$ and $\text{[5]}$, which is biased according to Eq. (1) in a voltage-$V$ range that is significant fraction of the superconducting gap $\Delta$, typically $eV \sim \Delta/2$. Specifically, we detail the microscopic processes, starting with the nonlocal pair amplitude, and next proceeding further with the Floquet-Andreev and the Floquet-Tomasch contributions to the current, finally uncovering the ultralong-distance Floquet-Tomasch octets. We demonstrate
in Appendix A that the Floquet-Tomasch effect for the current of pairs in a three-terminal Josephson junction and the two-terminal density of state oscillations in the Tomasch effect cannot be advocated to be at the origin of the ultralong-distance current of pairs in the three-terminal Josephson junction. In the first place, in the three-terminal configuration, the quantum processes coupling the density of states at one contact to the pairs at the other contacts are AC at the lowest-order in the tunneling amplitudes, and thus, they cannot be put forward as an explanation to the calculated three-terminal DC-current of quartets and higher-order clusters of Cooper pairs.

Figures 2a and 2b show the energy diagram for the lowest-order pair amplitude between the quantum dots $D_x$ and $D_{x'}$, corresponding to conversion of "spin-up electron on the dot $D_x$" into "spin-down hole on the dot $D_{x'}$". The processes on figures 2a and 2b start with electron-hole conversion at the $S_x-D_x-S_{x'}$ Josephson junction: local Floquet-Andreev reflection first increases the energy by 2eV (i.e., the energy of a Cooper pair taken from the lead $S_b$ biased at the voltage $V$). The process continues with nonlocal propagation from $D_x$ to $D_{x'}$ across $S_c$ in the hole-electron channel. Next, "local" inverse-Floquet hole-electron conversion takes place at the $S_x-D_{x'}-S_{b}$ Josephson junction. In the final state, spin-down hole is produced at zero energy on the quantum dot $D_{x'}$.

The condition $|2eV| < \Delta$ on the bias voltage $V$ (see figure 2b) implies conversion in the hole-electron channel over the superconducting coherence length $\xi_{ball}(\omega)$, see Eq. (5). This subgap process is referred to as "the Floquet-Andreev quartet pair amplitude".

Conversely, $|2eV| > \Delta$ on figure 2a implies nonlocal hole-electron conversion above the gap of $S_c$. This process is limited by the mesoscopic phase coherence length $\ell_\phi$ of the superconducting quasiparticles, and it is referred to as "the ultralong-distance Floquet-Tomasch pair amplitude" [see the forthcoming Eqs. (11)-(18)], in analogy with the Tomasch effect mentioned above in the Introduction.

Emergence of the ultralong-distance Floquet-Tomasch pair amplitude if $|2eV| > \Delta$ implies ultralong-distance nonlocality over $R_0 \sim l_\phi$, and quantum correlations in the $\varphi_q$-sensitive current, which is considered now.

Now, we "close the loop" on figures 3a and 3b with final zero-energy hole-electron conversion from $D_{x'}$ to $D_x$. The resulting $\varphi_q$-sensitive Floquet-Andreev quartet current is limited by the superconducting coherence length $\xi_{ball}(0)$, independently on whether $|2eV| < \Delta$ or $|2eV| > \Delta$.

Finally, we consider the higher-order process of the ultralong-distance Floquet-Tomasch octets having sin(2$\varphi_q$)-sensitivity and range limited by $\ell_\phi$. Figure 4 shows the corresponding diagram, see also figure 4b. Two nonlocal and two local hole-electron conversions are involved: (i) Nonlocally from $D_{x'}$ to $D_{x'}$ and from $D_{x'}$ to $D_x$ across $S_c$, and (ii) Locally between each $S_b$ and $S_b$, the $D_x$ and $D_{x'}$ quantum dots and $S_c$. Overall, the resulting sin(2$\varphi_q$)-sensitive octet current appears if the distance $R_0$ between the remote $S_x-D_x-S_b$ and $S_x-D_{x'}-S_b$ junctions reaches $R_0 \sim l_\phi$, such that $l_\phi \gg \xi_{ball}(0)$.

We conclude that figure 4 provides microscopic picture for the proposed ultralong-distance Floquet-Tomasch octets as an eight-fermion cluster originating from four Cooper pairs, see also figure 4b.

This physical picture suggests cross-over as $R_0$ increases from below to above $\xi_{ball}(0)$, i.e., from "the dominant sin $\varphi_q$ of the Floquet-Andreev quartets over $\xi_{ball}(0)$" to "the dominant sin(2$\varphi_q$) of the ultralong-distance Floquet-Tomasch octets over $l_\phi$". A cross-over to the higher-order-$n$ clusters of Cooper pairs is expected as the voltage values is reduced below $\Delta/2n$ (with $n$ an integer).

We proceed further with the models and methods in section III next with the analytical results in section IV and finally the theory is put to the test of the numerical calculations in section V.

### III. MODEL AND METHODS

We start in subsection III A with a brief description of the models used in the paper, i.e., the geometry and the Hamiltonians. Next, we present in subsection III B a central ingredient of the model, i.e., the connection between the Dynes parameter and the mesoscopic phase coherence length of the superconducting quasiparticles. The methods are mentioned in section III C.

#### A. Geometry and Hamiltonians

Now, we present the geometry and the Hamiltonians. Figures 1a, 1b and 1c show the device geometry: the T-shaped grounded superconducting lead $S_c$ connected via the two quantum dots $D_x$ and $D_{x'}$ to $S_b$ and $S_b$ biased at $V_{a,b} = \pm V$. Those figures represent quasi-one-dimensional superconducting nanowire quantum dots similar to Ref. 31. The distance between $D_x$ and $D_{x'}$ is denoted by $R_0 = |R'| - |R|$.

Now, we provide the Hamiltonians. The BCS Hamiltonian of each infinite superconducting lead with gap $\Delta$ and phase $\varphi$ is given by

$$\mathcal{H}_{BCS} = -W \sum_{i,j} \sum_\sigma \left( c_{i,\sigma}^+ c_{j,\sigma} + c_{j,\sigma}^+ c_{i,\sigma} \right) \tag{4}$$

$$- \Delta \sum_i \left( e^{i\varphi} c_{i,\uparrow}^+ c_{i,\downarrow} + e^{-i\varphi} c_{i,\downarrow}^+ c_{i,\uparrow} \right), \tag{5}$$

where, again, $\sigma = \uparrow, \downarrow$ is the projection of the spin along the quantization axis, and $\varphi$ takes the values $\varphi_a, \varphi_b$ or $\varphi$, according to which of the superconducting lead $S_a$, $S_b$ or $S_c$ is considered. The notation $(i,j)$ in Eq. (4) stands for pairs of neighboring sites on a three-dimensional (3D) tight-binding lattice, and the label $i$ in Eq. (5) runs over all tight-binding sites.

The tunnel Hamiltonian couples the tight-binding sites on both sides of the contacts:

$$\mathcal{H}_f = -J \sum_{i,j} \sum_\sigma \left( c_{i,\sigma}^+ c_{j,\sigma} + c_{j,\sigma}^+ c_{i,\sigma} \right), \tag{6}$$
where \( \langle i, j \rangle \) in Eq. (6) denotes the pairs of corresponding tight-binding sites on both sides of the two-dimensional (2D) interface.

The Hamiltonian of a direct-gap semiconductor making the quantum dots on figure 5 is inspired by Ref. 95. We take the following Hamiltonian in the infinite 3D bulk limit:

\[
\mathcal{H}_1 = \sum_{q} \sum_{\sigma} \frac{|q|^2}{2m_e} a_{q,\sigma}^+ a_{q,\sigma} - \sum_{\sigma} \left( E_g + \frac{|q|^2}{2m_h} \right) b_{q,\sigma}^+ b_{q,\sigma}, \tag{7}
\]

where \( a_{q,\sigma}^+ \) or \( b_{q,\sigma}^+ \) create spin-\( \sigma \) fermions with the wave-vector \( q \) in the conduction or valence band, and \( E_g \) is the value of the direct gap. We will use in section IV the fact that the dispersion relations appearing in Eq. (7) have extrema at the wave-vector \( q^* = 0 \).

Considering the \( \langle a, \alpha \rangle \) pair of tight-binding sites making the contact at the interface between the superconductor \( S_a \) and the quantum dot \( D_a \) (see figure 5), the local creation operator \( c_{a,\sigma}^+ \) on the surface \( D_a \) is defined as a sum over the quantum numbers \( n_1 \) and \( n_2 \) of the \( a_{n_1,\sigma}^+ \) and \( b_{n_2,\sigma}^+ \) creation operators associated to both conduction and valence band respectively:

\[
c_{a,\sigma}^+ = \sum_{n_1} \varphi_{a,n_1}(R_a) a_{n_1,\sigma}^+ + \sum_{n_2} \varphi_{b,n_2}(R_a) b_{n_2,\sigma}^+, \tag{8}
\]

where we assumed a quantum dot with finite dimension, and the tight-binding site labeled by \( \alpha \) is at the space coordinate \( R_a \). In Eq. (8), the quantum numbers \( n_1 \) and \( n_2 \) label the states of the quantum dot with finite dimension, possibly with irregularities in its shape, and having Eq. (7) as its bulk Hamiltonian. The notations \( \varphi_{a,n_1}(R_a) \) and \( \varphi_{b,n_2}(R_a) \) stand for the corresponding conduction and valence band wave-functions.

The zero-dimensional (0D) quantum dot on figure 6 has level at zero energy. Thus, the corresponding Hamiltonian is \( \mathcal{H}_1' = 0 \).

The quantum dots are connected with highly transparent interfaces to the leads, which is why the Coulomb interaction is included neither in Eq. (1) nor in \( \mathcal{H}_1' = 0 \). For instance, the recent experiments on Andreev molecules do not seem to require Coulomb interactions as a central ingredient, because of the highly transparent interfaces.

Zero temperature is assumed throughout the paper. Nontrivial quasiparticle populations can be produced at zero temperature by driving normal current between two attached normal leads. An interesting theoretical and experimental question is to address whether driving normal current can result in change of sign of the quartet critical current, similarly to two terminals, see Refs. 96 and 97.

The scattering approach or the Keldysh Green’s functions were complementary used in the past to address superconducting junctions, see for instance Refs. 99–101 for a single superconducting weak link. Both approaches have their own advantages. For instance, the scattering matrix calculations and the wave-function approach allow for semiclassical calculations, see Refs. 48 and 102. Microscopic Green’s functions produce efficient algorithms to address the general conditions of high transparencies and large current bias, see for instance Ref. 94.

In the following, we rely on the Keldysh Green’s functions, on the basis of the algorithms that were developed over the last few years.

We also implement the simplifying assumption of a ballistic superconductor, similarly to the McMillan-Anderson and the Wolfram-Lehman papers on the Tomashch effect. Taking the ballistic limit yields considerable simplifications in the calculations, see below. Disorder in the superconductors could be introduced in the future on the basis of the Usadel equations. Another possible approach is to assume perturbation theory in the strength of the nonlocal processes between the two quantum dots, see the forthcoming section IV.
and to average over disorder the pairs of nonlocal Green’s functions connecting both quantum dots. The 16 Nambu components of the advanced-advanced transmission modes (see Ref. [20]) would then have to be generalized to the Keldysh contour and to energy outside the superconducting gap.

**B. The mesoscopic phase coherence length of the superconducting quasiparticles**

In this subsection, we relate the mesoscopic phase coherence length \( l_\phi \) of the superconducting quasiparticles to the Dynes parameter \( \eta_\phi \).[17][104][107]

By the time-energy uncertainty relation, and by the correspondence between the time and length scales, a characteristic length \( \hbar v_F / E_0 \) is associated to any energy scale \( E_0 \). To the Fermi energy \( E_F \) is associated the Fermi wave-length \( \lambda_F \), which is much smaller than the superconducting coherence length \( \xi_{ball}(0) \) that is related to the superconducting gap \( \Delta \). The characteristic length \( l_\phi \) is conjugate to the Dynes parameter \( \eta_\phi \), and it phenomenologically accounts for the quantum-to-classical cross-over of the propagating superconducting quasiparticles, due to inelastic scattering and energy relaxation. Then, \( l_\phi \) is much larger than the superconducting coherence length \( \xi_{ball}(0) \), i.e. \( l_\phi \gg \xi_{ball}(0) \), because the Dynes parameter \( \eta_\phi \) is much smaller than the superconducting gap \( \Delta \), i.e. \( \eta_\phi \ll \Delta \), see Refs. [17][104][107]. The length scale \( l_\phi \) has to cross-over to its normal-state value \( \hbar v_F / \xi_0 \) as the energy \( \omega \) crosses-over above \( \omega \geq 2 \Delta \). This \( l_\phi \) naturally receives the interpretation of defining the "limit of the quantum world" as far as the superconducting quasiparticle propagation is concerned.

Now, within this phenomenological “Dynes picture”, we provide analytical expressions for the mesoscopic phase coherence length \( l_\phi \) of the superconducting quasiparticles as a function of the energy \( \omega \).

The evanescent Bogoliubov-de Gennes wave-functions decay exponentially like \( \sim \exp \left( -R / \xi_{ball}(\omega - i\eta_\phi) \right) \) from the interface at the subgap energy \( |\omega| < \Delta \), see also the Green’s function given by Eq. (83). Then, the superconducting coherence length \( \xi_{ball}(\omega - i\eta_\phi) \) can be continued to energies \( |\omega| > \Delta \) outside the gap, and it has the following real and imaginary parts:

\[
\frac{1}{\xi_{ball}(\omega - i\eta_\phi)} = \text{Re} \left( \frac{1}{\xi_{ball}(\omega - i\eta_\phi)} \right) + i \text{Im} \left( \frac{1}{\xi_{ball}(\omega - i\eta_\phi)} \right),
\]

which yields damping and oscillations:

\[
\exp \left( -\frac{R}{\xi_{ball}(\omega - i\eta_\phi)} \right) = \exp \left[ -R \text{Re} \left( \frac{1}{\xi_{ball}(\omega - i\eta_\phi)} \right) \right] \times \exp \left[ -i R \text{Im} \left( \frac{1}{\xi_{ball}(\omega - i\eta_\phi)} \right) \right].
\]

We define the inverse damping length as

\[
\frac{1}{l_\phi} = \text{Re} \left( \frac{1}{\xi_{ball}(\omega - i\eta_\phi)} \right),
\]

with \( |\omega| > \Delta \).

We note that \( \text{Re} \sqrt{\Delta^2 - (\omega - i\eta_\phi)^2} = \rho \cos(\theta/2) \), where \( \rho^2 \exp(i\theta) = \Delta^2 - \omega^2 + \eta_\phi^2 + 2i\eta_\phi \omega \). Using \( \cos \theta = 2\cos^2(\theta/2) - 1 \) leads to

\[
\frac{1}{l_\phi} = \frac{1}{\sqrt{2}} \left( \frac{\left( \Delta^2 - \omega^2 + \eta_\phi^2 \right)^{1/2} + \Delta^2 - \omega^2 + \eta_\phi^2}{\Delta^2 - \omega^2 + \eta_\phi^2} \right)^{1/2}. 
\]

Assuming \( \eta_\phi \ll \Delta \) and \( |\omega| > \Delta \) yields

\[
\left\{ \left( \Delta^2 - \omega^2 + \eta_\phi^2 \right)^{1/2} + \Delta^2 - \omega^2 + \eta_\phi^2 \right\}^2 \]

\[
\approx \left( \Delta^2 - \omega^2 + \eta_\phi^2 \right)^{1/2},
\]

which implies the ultralong-distance effect corresponding to \( \xi_{ball}(0) \gg \Delta \) in Eq. (8). The Dynes ratio \( \eta_\phi / \Delta \ll 1 \) is small in the experiments, which implies the ultralong-distance effect corresponding to \( l_\phi / \xi_{ball}(0) \gg 1 \) in Eq. (18).

Thus, Eq. (18) supports the idea presented in the Introduction, i.e. within this Dynes picture, the mesoscopic phase coherence length \( l_\phi \) of the superconducting quasiparticles is orders of magnitude larger than the zero-energy superconducting coherence length \( \xi_{ball}(0) \) in a typical energy window that can roughly be estimated as \( |\omega| \approx 2 \Delta \). This typical spectral window for emergence of the ultralong-distance Floquet-Tomasch effect reflects the coexistence of both features of the
normal and superconducting states, \textit{i.e.} long $l_\phi$ and sizeable nonlocal Andreev processes.

Controlling the electromagnetic environment as in Ref.[106] can reduce the value of the Dynes parameter $\eta_S$ by orders of magnitude, and produce large value of $l_\phi$ according to Eqs. (11)-(18). This can also be used to rule out the coupling to the electromagnetic environment as the origin of the quartet line. In the previous Grenoble and Weizmann group experiments,[31] a device fabricated with remote junctions did not produce the quartet line in spite of the same electromagnetic environment as in the device with close junctions.

C. Methods

The analytical and numerical calculations presented in sections IV and V respectively are based on the Keldysh Green’s functions. Details about the methods are provided in Appendix B.

IV. ANALYTICAL RESULTS

In this section, we assume that the quantum dots are fabricated with direct-gap semiconductors [see Eq. (7)], and we map “the model I” on figure 3 into “the reduced model II” on figure 4. We also provide analytical results demonstrating the Floquet-Andreev quartets and the ultralong-distance Floquet-Tomasch octets, discuss the absence of dephasing in propagation to the two-terminal density of states in the Tomasch experiments and for the pair current in the here considered three-terminal Josephson junction. However, the quantum processes are distinct from each other and it turns out that the nonlocal coupling between the density of states at one contact and the pairs at the other contact is AC in the three-terminal Josephson junction.

Specifically, starting with the model I in figure 3 we assume that the Nambu Green’s function of each quantum dot $D_x$ or $D_{x'}$ fulfills the following “generalized star-triangle relation”, \textit{i.e.} we propose the following for the quantum dot $D_x$:

\[
\hat{g}_{x_1 \alpha_1, x_2 \alpha_2} = \hat{g}_{x_1 \alpha_1, x_3 \alpha_3} \hat{g}_{x_3 \alpha_3, x_2 \alpha_2}, \quad \hat{g}_{x_1 \alpha_1, \gamma_1} = \hat{g}_{x_1 \alpha_1, x_3 \alpha_3} \hat{g}_{x_3 \alpha_3, \gamma_1}.
\]

The assumption of resonance at zero energy implies $\hat{g}_{x_1 \alpha_1} \sim 1/(\omega - i\eta)$, see the discussion following Eq. (B1) in Appendix B. We consider that the quantum dots have minimum at the wave-vector $q' = 0$ in their dispersion relation, see Eq. (7). We assume that the contact dimension is small compared to $2\pi/q^*$ and that the size of the quantum dots is small compared to the decay length of the evanescent wave-functions on the dot. Then, $\hat{g}_{x_1 \alpha_1, \gamma_1}$ and $\hat{g}$ are roughly independent on $p_1$, $p_2$, and $\hat{g}$ is the matrix square root of the residue in Eq. (B2).

The Green’s functions are matrices in Nambu and in the enlarged space of the harmonics of the Josephson frequency. The labels $p_1$, $p_2$ running over the tight-binding sites at the interfaces are now made implicit [see Eqs. (19)-(20)].

The fully dressed Green’s function $G_{x,x'}$ on the dot $D_x$ can be “expanded in nonlocality” according to

\[
\hat{G}_{x,x'} = \hat{L}_{x,x'} + \hat{L}_{x,x'} \hat{K}_{x,x'} \hat{L}_{x,x'} + \hat{L}_{x,x'} \hat{K}_{x,x'} \hat{L}_{x,x'} \hat{K}_{x',x} \hat{L}_{x',x} + \ldots.
\]

where $L_{x,x'}$ and $L_{x',x}$ describe “local” dressing at the $S_x$-$D_x$-$S_c$ and $S_{x'}$-$D_{x'}$-$S_p$ junctions, and the matrices $\hat{K}_{x,x'}$ and $\hat{K}_{x',x}$ correspond to nonlocal propagation from $x$ to $x'$ and from $x'$ to $x$ respectively, see Appendix C. An expansion similar to Eqs. (21)-(24) was previously developed for the nonlocal conductance of $F_{S}SF_{S'}$ or $N_{SP}N_{SP}$ beam splitters, see Ref. [74]. Here, the small parameter for nonlocality of the Floquet-Andreev quartets is $\epsilon_0 = \exp[-2R_0/\xi_{ball}(0)]$, due to transmission of quasiparticles \textit{via} evanescent states in the subgap energy window. The small parameter for the Floquet-Tomasch octets is $\epsilon_0 = \exp[-2R_0/l_\phi(\omega)]$ instead of the previous $\epsilon_0$, corresponding to propagation \textit{via} plane waves in a spectral window above the gap of $S_c$, and damping over the mesoscopic phase coherence length $l_\phi(\omega)$, see Eqs. (11)-(16).

The first term in Eq. (21) does not couple the two quantum dots. The Keldysh component of the second term in Eq. (22) is the following:

\[
\Sigma_{x',a} g^{\Sigma}_{a,a} \sim (\Sigma_{x',a} \hat{g}_{x',x} \hat{L}_{x,x'} \hat{K}_{x',x} \hat{L}_{x,x'} \Sigma_{a,a} g a a)_{x',x}.
\]

Specifying the Nambu labels corresponding to anomalous propagation between $D_x$ and $D_{x'}$ leads to

\[
(\Sigma_{x',a} g_{a,a}^{\Sigma})_{(1,1)} \sim (\Sigma_{x,a} \hat{g}_{x,x} \hat{L}_{x,x}(1,1) \hat{K}_{x',x} \hat{L}_{x,x'}(1,2) \hat{K}_{x',x'}(2,1) \hat{L}_{x',x'}(2,2) \hat{g}_{x,a}(2,2) \Sigma_{x,a}(2,1) \Sigma_{a,a}(2,1))_{x',x}.
\]

Within this approximation, the Floquet-Tomasch quartets and octets propagate a pair of nonlocal Green’s functions between the two quantum dots, where Eq. (26) also captures “local” dressing by multiple Andreev reflections at each S-dot-S Josephson junction.
The Floquet-Andreev quartets correspond to

\[
\left(\Sigma_{a,\alpha}G_{a,a}^{-}\right)_{(1),(1)}/(0,0) \simeq \left(\Sigma_{a,\alpha}(1,1)/(0,1)\tilde{g}_{a,x}(1,1)/(1,1)\tilde{L}_{x,x}(1,1)/(1,1)\tilde{K}_{x,x}(1,2)/(1,1)\tilde{L}_{x',x'}(1,2)/(1,1)\right)^{+-},
\]

where the “\((\tau_1, \tau_2)/(\eta_1, \eta_2)\)” labels are used for the Nambu and Floquet labels respectively. Both \(\tilde{K}_{x,x}\) and \(\tilde{K}_{x',x'}\) entering Eq. (27) are of order \(\mathcal{E}_\theta\) if \(R_0 \gtrsim \xi_{ball}(0)\), due to the corresponding dominant contribution of the subgap energy window. Thus, \(\left(\Sigma_{a,\alpha}G_{a,a}^{-}\right)_{(1),(1)}\) in Eq. (26) is of order \(\mathcal{E}_\theta^2\).

The Floquet-Tomasch Keldysh Green’s function is given by

\[
\left(\Sigma_{a,\alpha}G_{a,a}^{\pm}\right)_{(1),(1)}/(0,0) \simeq \left(\Sigma_{a,\alpha}(1,1)/(0,1)\tilde{g}_{a,x}(1,1)/(1,1)\tilde{L}_{x,x}(1,1)/(1,1)\tilde{K}_{x,x}(1,2)/(1,1)\tilde{L}_{x',x'}(2,2)/(1,1)\right)^{+-},
\]

where \(\tilde{K}_{x,x}(1,2)\) and \(\tilde{K}_{x',x'}(1,2)\) entering Eq. (28) are both of order \(\mathcal{E}_\theta\) if \(R_0 \gtrsim \xi_{ball}(0)\). Thus, \(\left(\Sigma_{a,\alpha}G_{a,a}^{\pm}\right)_{(1),(1)}\) in Eq. (28) is of order \(\mathcal{E}_\theta^2\).

Eqs. (27)-(28) imply that the current \(I_q\) on the quartet line is expressed as summation over \(c_1, c_2\) and \(c_1', c_2'\) at the \(D_a-S_c\) and \(S_c-D_c\) interfaces respectively, see figure 5. \(I_q = \Sigma_{c_1, c_2, c_1', c_2'} I'_{c_1, c_1'} c_2, c_2'\). Then, Eq. (B-8) in Appendix B yields

\[
I_q = \sum_{c_1, c_2, c_1', c_2'} I'_{c_1, c_1'} c_2, c_2' \cos kFR_{c_1, c_1'} \cos kFR_{c_2, c_2'}. \tag{29}
\]

Gathering the Green’s functions in a pair-wise manner\textsuperscript{[108][109]} yields \(I_q \simeq \sum_{c_1, c_2, c_1', c_2'} I'_{c_1, c_1'} c_2, c_2'\) and

\[
I_q \approx \frac{k_F}{2\pi} \int_{R_0}^{R_0+2\pi/k_F} I_q(R) dR, \tag{30}
\]

where \(I_q(R)\) is the spectral current of the “reduced model II” on figure 5 at the distance \(R\) between the 0D quantum dots.

Thus, the use of direct-gap semiconductor quantum dots allows replacing “the multichannel contacts of the model I” by “the OD quantum dots of the reduced model II” while averaging over \(\psi_F\) in Eq. (B-4). We also singled-out the Floquet-Andreev quartet and the ultralong-distance Floquet-Tomasch octet contributions to the current, which supports the physical picture of the preceding sections \([II]\) and \([III]\) and the numerical results of the forthcoming section \([V]\).

We also note that biasing at \(eV = \pm \Delta/2\) produces coexisting gap edge singularities of \(S_a\) and \(S_b\). This is expected to result in large values for the quartet and octet critical currents \(I_{q,c} \sin \varphi_0\) and \(I_{o,c} \sin(2\varphi_0)\), as for perfectly transparent contacts. The following scaling form of \(|I_{q,c}|\) and \(|I_{o,c}|\) at the voltages \(eV = \pm \Delta/2\) can be conjectured:

\[
|I_{q,c}| \approx \frac{e}{\hbar} \exp \left(-\frac{2R_0}{\xi_{ball}(0)}\right), \tag{31}
\]

\[
|I_{o,c}| \approx \frac{e}{\hbar} \exp \left(-\frac{2R_0}{\varphi_0}\right), \tag{32}
\]

Both \(|I_{q,c}|\) and \(|I_{o,c}|\) are expected to be reduced if the bias voltage is detuned from \(\pm \Delta/e\). This Eq. (32) will further be considered in the next section on the numerical data.

Finally, we underline consistency with Ref. 92 regarding robustness with respect to dephasing between the corresponding pairs of Green’s function. The superconducting Green’s function \(\tilde{g}_{\mathcal{A}}^{\mathcal{K}}\) in Eq. (B4) is rewritten as

\[
\tilde{g}_{\mathcal{A}}^{\mathcal{K}} = \frac{1}{W} \frac{1}{k_F R} \exp \left[-\frac{R}{\xi_{ball}(\omega - i\varphi)}\right] \times \left[\cos \psi_F \mathcal{M}_{\cos}\left(\frac{\omega}{\Lambda}\right) + \sin \psi_F \mathcal{M}_{\sin}\left(\frac{\omega}{\Lambda}\right)\right], \tag{33}
\]

where

\[
\mathcal{M}_{\cos}\left(\frac{\omega}{\Lambda}\right) = \frac{1}{\sqrt{\Delta^2 - (\omega - i\varphi)^2}} \times \left(\begin{array}{ccc}
\frac{-\omega - i\varphi}{\Delta - i\varphi} & \frac{\Delta - i\varphi}{\Delta + i\varphi} \\
\frac{\Delta + i\varphi}{\Delta - i\varphi} & \frac{-\omega - i\varphi}{\Delta + i\varphi}
\end{array}\right), \tag{34}
\]

and \(\mathcal{R} = |x - y|\) is the distance between \(x\) and \(y\). We assume that the Fermi wave-length \(\lambda_F = 2\pi/k_F\) is much smaller than all other length scales:

\[
\text{Re} \left[\frac{1}{\xi_{ball}(\omega - i\varphi)}\right] \ll k_F \tag{37}
\]

\[
\text{Im} \left[\frac{1}{\xi_{ball}(\omega - i\varphi)}\right] \ll k_F. \tag{38}
\]

In addition, the characteristic dimension \(R_1\) of the quantum dot is such that \(R_1 \ll \xi_{ball}(0)\), which implies that the oscillations are not washed-out by extended contacts. Then, using the notation

\[
\langle \ldots \rangle_{\mathcal{A}} = \frac{k_F}{2\pi} \int_{R_0}^{R_0+2\pi/k_F} dR \tag{39}
\]

for averaging over \(R\) in the interval \([R_0, R_0 + 2\pi/k_F]\), see Eq. (30), we express the averaging of the pairs of Nambu Green’s functions as follows:
The quartet phase is \( \phi \). The couplings between the quantum dots and the superconducting leads are the following:

\[ R \phi \]

The quartet phase variable is set to \( \phi_0/2\pi = 0.1 \). The Dynes parameter is \( \eta_5/\Delta = 10^{-3} \), thus with \( \xi_0^{(\text{max})} = 10^3 \xi_0 \), where \( \xi_0 \) is a short notation for \( \xi_{\text{ball}}(0) \).

The quartet phase variable is set to \( \phi_0/2\pi = 0.1 \), see the forthcoming figure 9 for the \( \phi_0 \)-sensitivity of the quartet current at fixed separation \( R_0/\xi_{\text{ball}}(0) \). The current is in units of \( e\Delta/h \).

\[
\langle \langle \hat{g}^{A}_{x,y} \left( \frac{\omega_1}{\Delta} \right) \otimes \hat{g}^{A}_{x,y} \left( \frac{\omega_2}{\Delta} \right) \rangle \rangle \simeq \frac{1}{2W^2} \left( \frac{k_F R}{\Delta} \right)^2 \exp \left\{ \left( -\frac{R}{\xi_{\text{ball}}(\omega_1 - i\eta_5)} \right) \right\} \exp \left\{ \left( -\frac{R}{\xi_{\text{ball}}(\omega_2 - i\eta_5)} \right) \right\} \times \left[ \hat{H}_{\cos} \left( \frac{\omega_1}{\Delta} \right) \otimes \hat{H}_{\cos} \left( \frac{\omega_2}{\Delta} \right) + \hat{H}_{\sin} \left( \frac{\omega_1}{\Delta} \right) \otimes \hat{H}_{\sin} \left( \frac{\omega_2}{\Delta} \right) \right] .
\]

The corresponding anomalous components involve one or two nonlocal Andreev electron-hole or hole-electron conversion. They take sizeable values if \( \omega_1, \omega_2 \) are typically in the energy window \( 0 < |\omega_1|, |\omega_2| < 2\Delta \) instead of being strictly inside the gap according to \( 0 < |\omega_1|, |\omega_2| < \Delta \). This implies that the ultralong-distance effect holds for all of the quantum electron-hole conversion processes captured by Eq. (40), and being characterized by different sets of the corresponding 16 Nambu labels. As a consequence, both the density of state oscillations of the two-terminal Tomasch effect and the clusters of Cooper pairs in the three-terminal Josephson junction are characterized by the corresponding ultralong-distance coupling, see also Appendix A where the demonstration starts from the different point of view of the open boundary conditions considered by Wolfram and Lehman in Ref. 93. However, it is also shown in this Appendix A that the coupling between the density of states at one contact and the pairs at the other contact is AC in the three-terminal Josephson junction. Thus, those AC density of state oscillations in a three-terminal Josephson junction cannot explain the following numerical data on the DC-current of clusters of Cooper pairs also with three superconducting terminals.

To interpret the finite electron-hole or hole-electron conversion amplitude above the gap, in a characteristic spectral window \( |a| \lesssim 2\Delta \), we refer to Fig. 7a in the Blonder-Tinkham-Klapwijk approach[110], showing the sizeable An-
The effect of the Dynes parameter on the ultralong-distance effect: The figure shows the symmetric current $I_{\text{sym}}$ defined by Eq. (41) for a $S_a$-$D_x$-$S_a$-$D_x$-$S_b$ three-terminal Josephson junction biased at the voltages $(V_a, V_b, V_c) = (V, -V, 0)$. Panels a1-a4, b1-b4, c1-c4 and d1-d4 correspond to $\eta S/\Delta = 10^{-3}$, respectively. The values of the Dynes parameters are the following: $\eta S/\Delta = 10^{-3}$ (a1, b1, c1, d1), $\eta S/\Delta = 10^{-2.5}$ (a2, b2, c2, d2), $\eta S/\Delta = 10^{-2}$ (a3, b3, c3, d3) and $\eta S/\Delta = 10^{-1.5}$ (a4, b4, c4, d4). The other parameters are identical to figure 7. The current is in units of $e\Delta/h$.

In addition, the quasiparticles and pairs in the Tomasch oscillations in the two-terminal density of states copropagate over ultralong-distance, and they can be referred to as “the triplets correlations” between a single quasiparticle and a pair. Conversely, two copropagating pairs correspond to “the so-called quartets” in three-terminal Josephson junctions. A possibility is to speculate that enhanced condensation energy could be produced by those propagating Nambu modes acting like a “glue”, in addition to the mean field BCS pairing. Indeed, it would be interesting to consider analogies with the theory of the collective modes and to examine whether those “triplets” or “quartets” can possibly give rise to a collective state upon taking the Coulomb interaction or strong disorder into account.

V. NUMERICAL RESULTS

In this section, we provide selection of numerical data for the reduced model II, defined in the above section IV.

We successively introduce the calculations and present the ultralong-distance effect, see figures 7 and 8. Next, we present the cross-over from the Floquet-Andreev to the ultralong-distance Floquet-Tomasch octets in the quartet phase sensitivity of the current, as the distance between the dots is increased from $R_0/\xi_{\text{ball}}(0) \lesssim 1$ to $R_0/\xi_{\text{ball}}(0) \gtrsim 1$ and to $R_0/\xi_{\text{ball}}(0) \gg 1$, see figures 9 and 10.

The current of the $S_a$-$D_x$-$S_a$-$D_x$-$S_b$ double quantum dot three-terminal Josephson junction is obtained from the fully dressed Dyson-Keldysh equations to all orders in the tunneling amplitudes. Concerning the algorithms, the code is based on numerically exact implementation of the Dyson and Dyson-Keldysh Eqs. (B6)-(B7), see Appendix B. The Dyson Eq. (B6) is solved with recursive Green’s functions in energy and sparse matrix algorithms are used for the matrix products. Details about the algorithms can be found in the Appendix of Ref. 18.
FIG. 9. The cross-over from the Floquet-Andreev quartets to the ultralong-distance Floquet-Tomasch octets: The figure shows the symmetric current $I_{\text{sym}}$ defined by Eq. (41) for a $S_aD_cS_cS_b$ three-terminal Josephson junction biased at the voltages $(V_a, V_b, V_c) = (V, -V, 0)$, as a function of $\varphi_q/2\pi$ on the $x$-axis. The voltage values are $eV/\Delta = 0.5, 0.4, 0.3$ and $R_0/\xi_{\text{ball}}(0) = 0.4, 3.2, 25.6$. The couplings between the quantum dots and the superconducting leads are the following: $\Gamma_{x,a}/\Delta = \Gamma_{x,b}/\Delta = 0.25$ and $\Gamma_{x,\alpha}/\Delta = \Gamma_{x,\beta}/\Delta = 1$. The Dynes parameter is $\eta_S/\Delta = 10^{-3}$, thus with $I_{\varphi}^{(\text{max})} = 10^3\xi_b$, where $\xi_b$ is a short notation for $\xi_{\text{ball}}(0)$. The current is in units of $e\Delta/h$.

Based on symmetry arguments\cite{43,40} we implement the hopping amplitudes $J_{s,a} = J_{b,a}$, and $J_{s,b} = J_{b,b}$, thus with $\Gamma_{x,a} = \Gamma_{x,b}$ and $\Gamma_{x,\alpha} = \Gamma_{x,\beta}$ for the normal-state line-width broadening parameters $\Gamma_{\alpha} = J_{a}^2/W$. Then, we evaluate the current of the clusters of Cooper pairs as

$$I_{\text{sym}}\left(\frac{R_0}{\xi_{\text{ball}}(0)}, \frac{eV}{\Delta}, \varphi_q \right) = I_a\left(\frac{R_0}{\xi_{\text{ball}}(0)}, \frac{eV}{\Delta}, \varphi_q \right) + I_b\left(\frac{R_0}{\xi_{\text{ball}}(0)}, \frac{eV}{\Delta}, \varphi_q \right), \tag{41}\label{41}$$

where the currents $I_a$ and $I_b$ are transmitted into $S_a$ and $S_b$, and $I_{\text{sym}}$ in Eq. (41) is averaged over $kF \cdot R$ according to Eq. (30).

We start with the sensitivity of $I_{\text{sym}}(R_0/\xi_{\text{ball}}(0), eV/\Delta, \varphi_q/2\pi)$ on the distance $R_0/\xi_{\text{ball}}(0)$ between the quantum dots $D_a$ and $D_c$. The data on figure \ref{fig:9} show the current $I_{\text{sym}}$ as a function of $R_0/\xi_{\text{ball}}(0)$ at the fixed quartet phase $\varphi_q/2\pi = 0.1$ and for the reduced voltage values from $eV/\Delta = 0.3$ to $eV/\Delta = 1.2$ on panels a-j respectively. The numerical data on figure \ref{fig:9} feature complex pattern of the Floquet-Tomasch oscillations. The beatings are interpreted as interference between the wave-vectors of the quantum dot level Floquet replica. The numerical data on figure \ref{fig:9} fully confirm the physical picture of section \ref{sec:11} regarding the ultralong-distance Floquet-Tomasch oscillations. The value $\eta_S/\Delta = 10^{-3}$ of the Dynes parameter used in figure \ref{fig:9} implies $I_{\varphi}^{(\text{max})}/\xi_{\text{ball}}(0) = 10^3$, see Eqs. (11)-(16). This is compatible with emergence of sizeable $I_{\text{sym}}(R_0/\xi_{\text{ball}}(0), eV/\Delta, \varphi_q/2\pi)$ at $R_0/\xi_{\text{ball}}(0) = 100$ on figure \ref{fig:9}. By contrast, $R_0$ is limited by $R_0 < \xi_{\text{ball}}(0)$ in the recently considered Andreev molecules with all superconducting leads grounded\cite{44,29,27}, and in the $F_0SF_b$ and $N_aSN_b$ Cooper pair beam splitters, see Refs. \cite{54,77}. We also note that, strictly speaking, $\xi_{\text{ball}}(0)$ given by Eq. (2) and $I_{\varphi}^{(\text{max})}$ given by Eq. (17) are two independent length scales, in the sense that $I_{\varphi}^{(\text{max})}$ is not proportional to $\xi_{\text{ball}}(0)$. The current $I_{\text{sym}}$ was averaged over the oscillations at the scale of the Fermi wave-length $\lambda_F = 2\pi/k_F$ according to Eq. (30). Then, $\xi_{\text{ball}}(0)$ is the smallest length-scale to which the calculated $I_{\text{sym}}$ couples and it is illustrative to plot $I_{\text{sym}}$ as a function of $R_0/\xi_{\text{ball}}(0)$.

Figure \ref{fig:9} illustrates the effect of the Dynes parameter on the
Andreev-Floquet-Tomasch effect is strongly reduced by \( \eta_S/\Delta = 10^{-3} \), since in this voltage window, see the remarks related to Eqs. (31)-(32) in the preceding sections II, III and IV.

We also deduce from the \( \gamma \)-scales on figure 7 that the current \( I_{sym} \) reaches maximum around \( eV/\Delta \approx 1/2 \), i.e., \( I_{sym} \) for \( eV/\Delta = 0.4, 0.5 \) on figures 7b and 7c is one order of magnitude larger than for \( eV/\Delta = 0.3, 0.6 \) on figures 7a and 7d. The strong enhancement of \( I_{sym} \) at \( eV/\Delta = 1/2 \) is interpreted as the coinciding upper and lower gap edge singularities of \( S_0 \) and \( S_0 \) which are biased at \( \pm V = \pm \Delta/2e \), as if the contact transparencies would be enhanced by orders of magnitude in this voltage window, see the remarks related to Eqs. (31)-(32) in the previous section IV.

It is also visible on figures 8 and 9 that the current \( I_{sym} \) is larger for \( eV/\Delta = 0.7 \) than for \( eV/\Delta = 0.8 \). The voltage-dependence of \( I_{sym} \) is indeed expected to be nonmonotonic, because of the interplay between the voltage-\( V \) sensitive peaks in the density of states coming from the quantum dot Floquet replica, and the BCS gap edge singularities, see the diagrams on figure 9.

The cross-over from the Andreev quartets to the ultralong-distance Floquet-Tomasch octets was proposed in section II as \( R_0/\xi_{ball}(0) \) is increased from \( R_0/\xi_{ball}(0) \gtrsim 1 \) and next to \( R_0/\xi_{ball}(0) \gg 1 \). Figures 9 and 10 show how \( I_{sym}(R_0/\xi_{ball}(0), eV/\Delta, \varphi_0/2\pi) \) depends on the quartet phase \( \varphi_0/2\pi \) at fixed values of the reduced voltage \( eV/\Delta \) and distance \( R_0/\xi_{ball}(0) \) between the quantum dots. The values \( eV/\Delta = 0.5, 0.4, 0.3 \) and \( R_0/\xi_{ball}(0) = 0.4, 3.2, 25.6 \) are used on figure 9 and \( eV/\Delta = 0.5, 0.4, 0.3 \) and \( R_0/\xi_{ball}(0) = 0.4, 3.2, 25.6 \) are used on figure 10.

In general, the symmetric current \( I_{sym} \) has dominant quartet, octet or higher-order \( \varphi_0 \)-sensitivity, namely \( I_{sym} \sim \sin \varphi_0 \), \( I_{sym} \sim \sin(2\varphi_0) \) or \( I_{sym} \sim \sin(n\varphi_0) \) respectively.

The voltage \( eV/\Delta = 0.8 \) on figures 9a1, 9a2 and 9c1.
a^3 confirms the cross-over from the sin φ_q Andreev quanta
to the sin(2φ_q) ultralong-distance Floquet-Tomasch
octets as R_0/ξ_{ball}(0) is increased from R_0/ξ_{ball}(0) = 0.8 to
R_0/ξ_{ball}(0) = 3.2 and to R_0/ξ_{ball}(0) = 25.6. The dominant
sin φ_q and −sin φ_q are obtained for the small R_0/ξ_{ball}(0) = 0.4 and
for the intermediate R_0/ξ_{ball}(0) = 3.2 on figures 9-a1 and 9-a2, while the dominant sin(2φ_q) of the ultralong-
distance Floquet-Tomasch octets is obtained for R_0/ξ_{ball}(0) = 25.6 on figure 9-a3.

We also proposed in section II emergence of higher-order harmonics in the current-quartet phase relation as eV/Δ is
reduced. To illustrate this point, we now reduce the bias voltage to eV/Δ = 0.7 (see figures 9-b1, 9-b2 and 9-b3) and
to eV/Δ = 0.6 (see figures 9-c1, 9-c2 and 9-c3). The following
voltage values are also used on figure 10: eV/Δ = 0.5 (see figures 10-a1, 10-a2, 10-a3), eV/Δ = 0.4 (see figures
10-b1, 10-b2, 10-b3) and eV/Δ = 0.3 (see figures 10-c1, 10-c2, 10-c3). The dominant sin(3φ_q) harmonics emerges for
eV/Δ = 0.6, R_0/ξ_{ball}(0) = 25.8 on figure 9-c3, and for
eV/Δ = 0.5, R_0/ξ_{ball}(0) = 25.8, eV/Δ = 0.4, R_0/ξ_{ball}(0) =
25.8 on figures 10-a3 and 10-b3. The higher-order sin(4φ_q)
harmonics is also obtained for eV/Δ = 0.3, R_0/ξ_{ball}(0) = 25.8 on
figure 10-c3.

We note consistency with our previous results for a single
0D quantum dot. Namely, R_0/ξ_{ball}(0) = 0.4 and
R_0/ξ_{ball}(0) = 3.2 on figures 9-a1, 9-a2 and 9-c1 and on figures
10-a1, 10-a2 and 10-c1 feature the 0-to-π and π-to-0 cross-overs which were found in our previous Ref. 18.

To summarize, the numerical calculations confirm the physical
picture of section II Appendix A and the analytical results of section IV regarding the following items: (i) The ultralong
range of the effect and the way it depends on the Dynes parameter ratio η_β/Δ. (ii) The sensitivity on the quartet phase φ_q,
i.e. the cross-over from the Andreev quanta to the ultralong-distance Floquet-Tomasch octets as R_0/ξ_{ball}(0) is increased
from R_0/ξ_{ball}(0) ≲ 1 to R_0/ξ_{ball}(0) ≳ 1 and to R_0/ξ_{ball}(0) ≫ 1,
(iii) The voltage dependence of the effect, i.e. the emergence of higher-order harmonics at smaller voltages of the
voltage eV/Δ, and (iv) The emergence of large ultralong-distance signal if eV ≃ ±Δ/2, which becomes weaker if eV is tuned
away from ±Δ/2.

VI. DISCUSSION

In this section, we discuss consequences for probing the “quantumness” of the Floquet-Tomasch clusters of Cooper
pairs with quantum current-noise cross-correlations. We distinguish between theory (see subsection VI.A and possible
experiments (see section VI.B).

A. Quantum current-noise cross-correlations

The price to pay for nonlocal clusters of Cooper pairs over
the ultralong-distance R_0 ~ l_p is apparently to renounce to a “good Floquet qu-bit”. Considering that the bias voltage
energy eV is much smaller than the superconducting gap
Δ, the Floquet resonance line-width broadening δ is limited by multiple Andreev reflection \[ \frac{\pi}{2\delta} \] at least in the absence of “extrinsic” mechanism of relaxation. We previously reported \[ R_0 \sim l_p \] that δ ~ exp(−cΔ/eV) with c of order unity, i.e. the line-width broadening is exponentially small as eV/Δ is reduced. But here, the coupling to the continua of quasiparticles above the gap produces significant broadening of the Floquet resonances and small coherence time \[ R_0 \sim l_p \] at higher voltage values, from eV/Δ = 0.3 to eV/Δ = 1.2 on figures 7, 8 and 9.

This “poor Floquet qu-bit” does however not preclude emergence of quantum correlations at the ultralong distance
R_0 ~ l_p, because the Cooper pair clusters are composite objects made of both the “locally transmitted” and “nonlocally
split” Cooper pairs, see figure 11. It is known that, in general, breaking Cooper pairs produces quantum mechanical correla-
tions and entanglement, see the F_s F_s and the N_s N_s beam splitters.\[ \text{Nonvanishingly small zero-frequency quantum current-noise cross-correlations } S_{a,b} \neq 0 \text{ in a } S_s \text{-dot- } S_s \text{-dot- } S_b
\text{three-terminal Josephson junction at the ultralong } R_0 \sim l_p \text{ is a possibility for experimental demonstration of the quantum
nature of the ultralong-distance Cooper pair clusters.}

In fact, the quantum current-noise cross-correlation kernel
\[ S_{a,b}(\tau) = \hbar \int d\tau' K_{a,b}(\tau, \tau') \] (42)
was calculated by many authors, see for instance Ref. 101 and Eqs. (15)-(19) in our preceding Ref. 18.

\[ K_{a,b}(\tau, \tau') = \frac{e^2}{\hbar^2} \text{Tr} \]
\[ \{ \hat{J}_{\beta, b}(\tau) \hat{\xi}_b \hat{G}_{b,a}^{+}(\tau, \tau') \hat{J}_{\alpha, a}(\tau') \hat{\xi}_a \hat{G}_{a,b}^{-}(\tau', \tau) \} \]
\[ + \hat{J}_{\beta, b}(\tau) \hat{\xi}_b \hat{G}_{b,a}^{+}(\tau, \tau') \hat{J}_{\alpha, a}(\tau') \hat{\xi}_a \hat{G}_{a,b}^{-}(\tau', \tau) \]
\[ - \hat{J}_{\beta, b}(\tau) \hat{\xi}_b \hat{G}_{b,a}^{+}(\tau, \tau') \hat{J}_{\alpha, a}(\tau') \hat{\xi}_a \hat{G}_{a,b}^{+}(\tau', \tau) \]
\[ - \hat{J}_{\beta, b}(\tau) \hat{\xi}_b \hat{G}_{b,a}^{+}(\tau, \tau') \hat{J}_{\alpha, a}(\tau') \hat{\xi}_a \hat{G}_{a,b}^{+}(\tau', \tau) \]
\[ + (\tau \leftrightarrow \tau') \] (47)

where \( \hat{\xi}_q \) is a Pauli matrix, \( \tau, \tau' \) are the time variables and we assume S_s S_s S_s, three-terminal device which is connected to the tight-binding sites a -(α, β)-b with the hopping amplitudes \( I_{a, a} = I_{a, a} \) and \( I_{b, b} = I_{b, b} \). Eqs. (43)-(47) can be Fourier transformed from the time variables \( \tau, \tau' \) to the energies \( \omega = neV + \omega + m eV \), where n and m are two integers.

The nonvanishingly small current I.sym \( \neq 0 \) of the quartets, octets or higher-order clusters of Cooper pairs at the ultralong
\( R_0 \sim l_p \) implies nonvanishingly small Keldysh Green’s functions \( \hat{G}^{+,-} \) and \( \hat{G}^{-,+} \), see the corresponding expressions of the current in Eq. (41), Eq. (58) and Eqs. (B10)/(B13). Then, \( S_{a,b} \neq 0 \) at the ultralong \( R_0 \sim l_p \) emerges on the condition that \( \hat{G}^{+,-} \) and \( \hat{G}^{-,+} \) in Eqs. (43)-(47) take values in overlapping energy intervals, i.e. the bias voltage \( V \) should also be nonvanishingly small. In practice, the bias voltage energy eV is a significant fraction of the superconducting gap Δ.

Thus, within our model, the reported current I.sym \( \neq 0 \) implies quantum current-noise cross-correlations \( S_{a,b} \neq 0 \) due
to the quantum fluctuations of the current operators at the ultralong-distance $R_0 \sim I_\eta$. Possible quantum noise cross-correlation experiments are considered now.

**B. Proposed current cross-correlation experiments**

On the experimental side, the positive zero-frequency quantum current-noise cross-correlations of the quartets were predicted and measured in the Weizmann group experiment 8. In this experiment, absence of the quartet line and vanishingly small quantum current-noise cross-correlations $S_{a,b} = 0$ were obtained with a pair of “remote” Josephson junctions. It was then concluded that the “trivial effect” of the electromagnetic environment is not at the origin of the quartet resonance line. The Grenoble experiment also ruled out “extrinsic synchronization” by demonstrating absence of the quartet line with remote contacts in a metallic structure.

The bias voltage was very low with respect to the superconducting gap in the Weizmann group experiment 8, i.e. $eV \ll \Delta$. Here, we propose analogous measurement of the quantum current-noise cross-correlations at voltage values that are significant fractions of the gap. Typically $eV/\Delta$ is within the same range as on figures 7, 8, 9 and 10, i.e. from $eV/\Delta = 0.3$ to $eV/\Delta = 1.2$, given the above mentioned “gap edge singularity resonance” at $eV/\Delta = 1/2$. We propose to systematically vary the distance $R_0$ between the junctions, in comparison with the superconducting coherence length $\xi_{ball}(0)$ and the mesoscopic phase coherence length $l_\eta$. It is expected that the ultralong-distance Floquet-Tomasch clusters of Cooper pairs are above detection threshold, given the large signal in the Tomash experiments 73–77.

**VII. CONCLUSIONS**

Summary of the paper and final remarks are presented now. We provided evidence for ultralong-distance nonlocality and quantum correlations in $S_{\alpha \cdot \dot{S}_{\alpha \cdot \dot{S}_{\dot{S}}}}$ three-terminal Josephson junctions where the constituting $S_{\alpha \cdot \dot{S}_{\alpha}}$ and $S_{\dot{S}_{\alpha \cdot \dot{S}_{\dot{S}}}}$ are biased at opposite voltage on the line. We presented physical arguments in section II and Appendix A regarding the diagrammatic interpretation of nonlocality. Analytical theory was proposed in sections III and IV. We reduced the direct-gap semiconducting quantum dots to zero dimension, and demonstrated emergence of the Floquet-Andreev and Floquet-Tomasch currents limited by the relevant length scales of the superconducting coherence length $\xi_{ball}(0)$ and the mesoscopic phase coherence length of the superconducting quasiparticles $l_\phi$ respectively. The numerical calculations presented in section V reveal that the ultralong-distance Floquet-Tomasch clusters of Cooper pairs emerge if the separation $R_0$ between the Josephson junctions exceeds the superconducting coherence length $\xi_{ball}(0)$ by orders of magnitude, i.e. if $R_0 \gg \xi_{ball}(0)$. This results from a phenomenological description relying on the observation that the Dynes parameter $\eta_S \ll \Delta$ is much smaller than the gap $\Delta$, which implies that the corresponding mesoscopic phase coherence length $l_\phi \gg \xi_{ball}(0)$ of the superconducting quasiparticles is much larger than the superconducting coherence length $\xi_{ball}(0)$. In addition, in agreement with the physical arguments of section II the voltage values are significant fractions of the superconducting gap $\Delta$, typically $eV > \Delta/2n$ for a cluster of order $n$, where $n$ is an integer. The typical spectral window for the ultralong-distance effect is roughly estimated as $|\phi| \approx 2\Delta$. Namely, the ultralong-distance effect is obtained and nonlocal Andreev processes are still sizeable if $|\phi|$ is not large compared to the superconducting gap $\Delta$. In this spectral window, the superconducting quasiparticles behavior reflects both the normal- and the superconducting-state properties. The numerical data confirm the expectation that increasing $R_0/\xi_{ball}(0)$ from $R_0/\xi_{ball}(0) \lesssim 1$ to $R_0/\xi_{ball}(0) \gtrsim 1$ and to $R_0/\xi_{ball}(0) \gg 1$ yields cross-over from the sin $\phi_\eta$ to the sin $(2\phi_\eta)$-sensitivities of the Floqueta-Andreev quartets and the ultralong-distance Floquet-Tomasch octets respectively. Reducing $eV$ below $\Delta/2n$ produces higher-order-$n$ clusters of Cooper pairs and dominant sin$(n\phi_\eta)$ harmonics in the current, where $n$ is an integer.

The Tomash oscillations 73 were experimentally observed with superconducting film thickness $R_0$ as large as $R_0 = 33.2 \mu m$. Thus, in analogy with the Tomash experiment 73 we conjecture emergence of the ultralong-distance Floquet-Tomasch clusters of Cooper pairs if the separation between the $S_{\alpha \cdot \dot{S}_{\alpha}}$ and $S_{\dot{S}_{\alpha \cdot \dot{S}_{\dot{S}}}}$ Josephson junctions is made as large as $R_0 = 33.2 \mu m$.

This predicted ultralong-range $R_0 \sim I_\eta$ of the Floquet-Tomasch effect is spectacularly orders of magnitude above the corresponding $R_0 \sim \xi_{ball}(0)$ for overlapping Andreev bound states at $V = 0$ or for $F_aSF_b$ or $N_aSN_b$ Cooper pair beam splitters, see Refs. 54–77.

Finally, we show in Appendix A that our numerical experiments on the Floquet-Tomasch clusters of Cooper pairs and the two-terminal density of state oscillations in the Tomash experiment 89–91 both involve ultralong-distance behavior. But the microscopic processes are different, and, in a three-terminal configuration, the coupling between the density of states at one contact and the pairs at the other contact is AC and thus, it cannot be proposed as an explanation for our numerical experiments on the DC-current of the Cooper pair clusters.

To conclude, the length scale $l_\phi$ for the mesoscopic phase coherence of the superconducting quasiparticles was phenomenologically introduced in our description. The effect offers the possibility to directly probe quantum coherence of the superconducting quasiparticle states, and to bridge with the physics of quasiparticle poisoning 81–83 in connection with the tremendous interest in the superconducting circuits of quantum engineering. It seems that future experiments could be a guideline towards further progress in understanding this complex physics. Controlling the electromagnetic environment seems to be promising for producing small values of the Dynes parameter $\eta_S$ and long mesoscopic phase coherence $l_\phi$ of the superconducting quasiparticles, see Ref. 106.
ACKNOWLEDGEMENTS

Appendix A: Connection with the Tomasch experiment

In this Appendix, we complement the main text by drawing a parallel between the here considered nonlocal current-phase response of the Floquet-Tomasch effect, and the density of state oscillations in the Tomasch experiment. We also conclude to different quantum processes in the density of state oscillations of the Tomasch effect and the current of pairs in a three-terminal Josephson junction. Thus, the former cannot be used to explain our calculations on the latter.

1. Effects of a boundary

In this subsection, we start from a superconductor with open boundary conditions, according to Wolfram and Lehman in Ref. 93 and demonstrate that this implies nonlocality in the sense of Eq. (6) in Ref. 92 by McMillan and Anderson.

Namely, we consider that a finite-size region $S_0$ is defined in an infinite 3D superconductor. The “interior” and the “exterior” are denoted by $S_0$ and $\bar{S}_0$ respectively. Thus $S_0 + \bar{S}_0$ is an infinite 3D superconductor, see figure 11.

We assume that the two-dimensional (2D) surface of $S_0$ is practically realized with a collection of the Nambu hopping amplitudes denoted by $\Sigma_{S_0, \bar{S}_0}$ and $\Sigma_{S_0, S_0}$ for hopping between $S_0$ and $\bar{S}_0$ and between $\bar{S}_0$ and $S_0$ respectively. Those matrices $\Sigma_{S_0, \bar{S}_0}$ and $\Sigma_{S_0, S_0}$ have entries in the tight-binding sites making the $S_0$-$\bar{S}_0$ interface and in the Nambu labels (i.e. they are diagonal in the Nambu labels).

We denote by $g$ and $G$ the Green’s functions of $S_0 + \bar{S}_0$ and $S_0$ respectively. We obtain $G$ for $S_0$ by including the hopping self-energies $\tilde{\Sigma}_{S_0, \bar{S}_0} = -\Sigma_{S_0, \bar{S}_0}$ and $\tilde{\Sigma}_{S_0, S_0} = -\Sigma_{S_0, S_0}$ which cancel the plain 3D tight-binding amplitudes on the $S_0$-$\bar{S}_0$ boundary. Thus, $S_0$ is disconnected from $\bar{S}_0$ in the Green’ function $G$ which is fully dressed with the self-energy $\tilde{\Sigma}$.

The Dyson equations

\[
\left( I - g_{S_0, S_0} \Sigma_{S_0, S_0} \right) G_{S_0, S_0} - g_{S_0, S_0} \Sigma_{S_0, S_0} G_{S_0, S_0} = g_{S_0, S_0} \quad (A1)
\]

\[
- g_{S_0, \bar{S}_0} \tilde{\Sigma}_{S_0, S_0} G_{S_0, S_0} + \left( I - g_{S_0, \bar{S}_0} \tilde{\Sigma}_{S_0, \bar{S}_0} \right) G_{S_0, S_0} = g_{S_0, \bar{S}_0} \quad (A2)
\]

have the following solution:

\[
G_{S_0, S_0} = \left[ I - g_{S_0, S_0} \Sigma_{S_0, S_0} - g_{S_0, S_0} \tilde{\Sigma}_{S_0, S_0} \left( I - g_{S_0, S_0} \tilde{\Sigma}_{S_0, S_0} \right)^{-1} g_{S_0, S_0} \right]^{-1} \times \left( I - g_{S_0, S_0} \tilde{\Sigma}_{S_0, S_0} \right)^{-1} g_{S_0, S_0} \quad (A3)
\]

The density of states is sometimes called as “the local density of states” because it can be measured with a local probe. It turns out that the density of states in the Tomasch experiment nonlocally couples to all of the thin-film boundary, if the conditions are met, regarding the characteristic energy and length scales. Specifically, we consider $R_0 \lesssim l_\phi$, where $R_0$ is the linear dimension of $S_0$, see figures 11b and 11c. In addition, we assume that the energy is in the range $|\omega| \approx 2\Delta$, see the discussion in section III B. The phenomenological mesoscopic phase coherence length $l_\phi$ was introduced above in section III. Then, Eq. (A3) implies that all pairs of tight-binding sites at the boundary of $S_0$ are connected to each other by the matrix $G_{S_0, S_0}$ taking roughly similar order of magnitude for all pairs of sites at the boundary, on the conditions $R_0 \lesssim l_\phi$ and $\omega \approx 2\Delta$.

Eq. (A3) also implies that conversion of spin-up electron into spin-down hole (and vice-versa) is effective at the boundary of $S_0$, which directly leads to Eq. (6) in Ref. 92 see also figure 11. This implies compatibility of our diagrammatic description with both Refs. 92 and 93.
2. The corresponding diagrams

Now, we consider the electron-hole Nambu labels and examine a single framework for deducing the different quantum processes that lead to the Tomasch density of states oscillations and to the Floquet-Tomasch pair current in three-terminal Josephson junctions. Those quantum processes are characterized by the distinct diagrams on figures 11c, 11d, and Fig. 11e.

Eq. (6) in Ref. 92 can schematically be represented by the two-terminal “triangular diagram” on figure 11c. This quantum process involves Andreev reflection at the thin-film boundary in the sense of spin-up electron quasiparticle from $S_0$ being reflected as spin-down hole quasiparticle in $S_0$. Then, a pair transmitted from the quasiparticles states into the condensate of the same $S_0$, and the crystal lattice has to be free to move in order to absorb the recoil coming from conservation of momentum. The diagram on figure 11c involves electron-electron propagation in the left superconductors $S_a$ and electron-hole conversion in the right superconductor $S_b$. Thus, figure 11c encodes the Tomasch effect in the sense Ref. 92 i.e. the variations of the density of states at the left interface as a function of the electron-hole conversion at the other contact.

Conversely, figure 11d shows schematically the three-terminal diagram for the density of states. It does not form a loop and thus, in a three-terminal configuration, the response in the density of states at one contact in $S_g$ as a function of the pair amplitude in $S_e$ features AC-oscillations.

Finally, the current of pairs in a double Josephson junction biased at opposite voltages is captured by the “quartet butterfly energy diagram” on figure 11e, see also Ref. 14 and figures 3a and 3b in section II. On figure 11e, two pairs are taken from $S_0$, they exchange partners, a pair is transmitted into the left superconductors $S_a$ in the final state, and another one into $S_b$ according to the quartet process.

Thus, energy conservation implies that the “triangular diagram process” on figure 11c is DC in the two-terminal configuration of the Tomasch experiment but it becomes AC in the three-terminal Josephson biased at opposite voltages. By contrast the quartet diagram on figure 11e is DC and this is why our numerical calculations for the DC-ultralong-distance Floquet-Tomasch current of pairs cannot be interpreted in terms of the AC-density of state. Instead, they naturally receive the proposed interpretation of the quartets and higher-order clusters of Cooper pairs.

However, the straightforward wording of “the Floquet-Tomasch effect” is used throughout the paper for the three-terminal Josephson junction, in order to refer to the common origin of the ultralong-distance coupling in both cases.

Appendix B: Details on the methods

This subsection summarizes the method to evaluate the currents.

The calculation of the current starts with expression of the bare advanced and retarded Green’s functions.

The bare Green’s function of each quantum dot is given by $g_{dot}(\omega) = (\omega - \mathcal{H}_{dot} - i\eta)^{-1}$, where $\omega$ is the energy and $\mathcal{H}_{dot}$ is the quantum dot Hamiltonian. Assuming the energy levels $\epsilon_\alpha$ and the wave-functions $\langle x|\alpha \rangle$ (at the location $x$) yields the following electron-electron Green’s function between $x$ and $y$:

$$g_{x,y}^\Lambda(\omega) = \sum_\alpha \langle x|\alpha \rangle \frac{1}{\omega - \epsilon_\alpha - \epsilon_y - i\eta}\langle \alpha|y \rangle,$$

(B1)

where the gate voltage $V_g$-tunable energy $\epsilon_y$ fulfills the condition $\epsilon_0 + \epsilon_y = 0$ if $\alpha = \alpha_0$, yielding resonance at zero energy.

FIG. 11. Panel a shows how a finite-size superconductor is defined in a bulk 3D superconductor, $S_0$ and $S_b$ being the interior and the exterior respectively. Panel b shows nonlocality and a schematic representation of Eq. (6) in Ref. 92. Panel c shows the “triangular energy diagram” for the DC-local density of states in a two-terminal configuration, as in the Tomasch experiment. Panel d shows the AC-density of states in a three-terminal configuration, where $S_a$ and $S_b$ are biased at opposite voltage while $S_0$ is grounded. Panel e shows the three-terminal “butterfly quartet energy diagram” for the DC-transport of pairs and the Floquet-Tomasch effect, see also figure 5.
\( \omega = 0 \) (see figure 1 for the gates). Then, \( g_{xy}^A(\omega) \) is Eq. (B1) is approximated as
\[
g_{xy}^A(\omega) \simeq \frac{1}{\omega - \eta} \langle x|a_0\rangle\langle a_0|y \rangle. \tag{B2}
\]
The parameter \( \eta \) in Eq. (B1) is related to the strength of relaxation. It was found in Ref. [17] that tiny relaxation \( 0 < \eta \ll \Delta \) has huge effect on the quartet current, in comparison with the previous Ref. [16] where \( \eta = 0^+ \). However, the available experimental data[14] do not allow to demonstrate that \( 0 < \eta \ll \Delta \) in Ref. [17] is more relevant than \( \eta = 0^+ \) in Ref. [16]. This is why the approximation \( \eta = 0^+ \) is used in absence of further experimental input.

The 2 \times 2 Nambu representation has entries for spin-up electrons and spin-down holes:
\[
g_{xy}^A(t,t') = -i\theta(t-t') \left( \begin{array}{cc} \{c_{x,\uparrow}(t),c_{y,\uparrow}^+(t')\} & \{c_{x,\uparrow}(t),c_{y,\downarrow}^+(t')\} \\ \{c_{x,\uparrow}^+(t),c_{y,\uparrow}^-(t')\} & \{c_{x,\downarrow}(t),c_{y,\uparrow}^+(t')\} \end{array} \right), \tag{B3}
\]
where \( \{ \} \) denotes averaging in the stationary state, \( \{ \} \) is an anticommutator, \( x, y \) are the space coordinates and \( t, t' \) are the time variables.

Using Eq. (B3) and the Hamiltonian given by Eqs. (4)–(5), we find the expression of the bare superconducting Green’s function with gap \( \Delta \) and phase \( \varphi \):
\[
g_{xy}^A(\omega) = \frac{1}{W} \frac{1}{k_F R} \exp \left\{ -\frac{R}{\xi_{\text{ball}}(\omega-i\eta S)} \right\} \left[ \begin{array}{c} \frac{\cos \psi_F}{\sqrt{\Delta^2 - (\omega-i\eta S)^2}} \left( -i\eta S \Delta e^{i\varphi} - (\omega-i\eta S) \Delta e^{-i\varphi} \right) \\ + \sin \psi_F \left( \begin{array}{cc} -1 & 0 \\ 0 & 1 \end{array} \right) \right], \tag{B4}
\]
where \( R = |x-y| \) is the distance between \( x \) and \( y \) and \( \varphi = \varphi_a, \varphi_b, \varphi_c \) according to which of the \( S_a, S_b \) or \( S_c \) superconducting lead is considered. The phase \( \psi_F = k_F R \) in Eq. (B4) oscillates at the scale of the small Fermi wave-length \( \lambda_F = 2\pi/k_F \), where \( k_F \) is the Fermi wave-vector. The ballistic superconducting coherence length \( \xi_{\text{ball}} \) at the energy \( \omega \) is given by Eq. (3).

Considering first vanishingly small bias voltage \( V = 0 \), the Nambu hopping amplitude connecting each quantum dot to the superconductors takes the form
\[
\hat{f} = \begin{pmatrix} J_0 & 0 \\ 0 & -J_0 \end{pmatrix}, \tag{B5}
\]
where each contact has different \( J_0 \). For instance \( J_0 \equiv J_{a,a} \) at the \( a-a \) interface on figure 3 and \( J_0 \equiv J_{c,c}, J_{c',c'} \) and \( J_{b,b} \) at the \( c-c', c'-c' \) and \( b-b \) interfaces.

The fully dressed advanced and retarded Nambu Green’s functions \( \hat{G}^{AR} \) are deduced from the bare ones by use of the Dyson equation
\[
\hat{G}^{AR} = \hat{g}^{AR} + \hat{g}^{AR} \otimes \hat{f} \otimes \hat{G}^{AR}, \tag{B6}
\]
where \( \otimes \) denotes convolution over the time variables and summation over the specific tight-binding sites at both ends of the tunneling amplitude \( \hat{f} \) connecting the dots to the superconductors.

Assuming now voltage biasing on the quartet line according to Eq. (1), the superconducting phases \( \varphi_a(t), \varphi_b(t) \) and \( \varphi_c(t) \) of \( S_a, S_b \) and \( S_c \) evolve according to the Josephson relations mentioned in the Introduction. The overall quantum dynamics being time-periodic, the Fourier-transformed Nambu Green’s functions acquire the integer labels \( n, m \) regarding the harmonics \( (2m eV/h, 2meV/h) \) of the frequency \( 2eV/h \) associated to the voltage \( V \).

The fully dressed Keldysh Green’s function \( \hat{G}^{+,-} \) is given by [8,10]
\[
\hat{G}^{+,-} = (\hat{I} + \hat{G}^R \otimes \hat{f}) \otimes \hat{G}^{+,-} \otimes (\hat{I} + \hat{f} \otimes \hat{G}^A), \tag{B7}
\]
where the bare Keldysh Green’s function is \( \hat{g}^{+,-}(\omega) = n_F(\omega) [\hat{g}^R(\omega) - \hat{g}^A(\omega)] \), with \( n_F(\omega) \) the Fermi-Dirac distribution function i.e. \( n_F(\omega) = \theta(\omega - \omega) \) in the limit of zero temperature, with \( \theta(x) = 1 \) if \( x > 0 \) and \( \theta(x) = 0 \) if \( x < 0 \).

The current is next deduced from \( \hat{G}^{+,-} \) given by Eq. (B7). For instance, the current through the \( a-a \) interface at time \( t \) is given by [9]
\[
I_{a-a}(t) = \frac{2e}{\hbar} \sum_p \left[ J_{ap,ap} \hat{G}_{ap,ap}^{-}(t,t) - J_{ap,ap} \hat{G}_{ap,ap}^{+}(t,t) \right] \tag{B8}
\]
The subscript “(1,1)” in Eq. (B8) stands for the electron-electron Nambu component. Eq. (B8) can be expressed as
\[
J_{a,a}(\omega) = \int \frac{d\omega}{2\pi} \sum_p \left( J_{ap,ap} \hat{G}_{ap,ap}^{+,-}(1,1)/(0,0) \right) \tag{B9}
\]
where the spectral current takes the form
\[
\hat{J}_{a,a}(\omega) = \sum_p \left[ \left( J_{ap,ap} \hat{G}_{ap,ap}^{+,-}(1,1)/(0,0) \right) \right] - \left( J_{ap,ap} \hat{G}_{ap,ap}^{+,-}(2,2)/(0,0) \right) \tag{B10}
\]
- \left( J_{ap,ap} \hat{G}_{ap,ap}^{+,-}(1,1)/(0,0) \right) \tag{B11}
+ \left( J_{ap,ap} \hat{G}_{ap,ap}^{+,-}(2,2)/(0,0) \right). \tag{B12}
\]
The subscripts “(1,1)” and “(2,2)” correspond to the “electron-electron” and “hole-hole” Nambu components and “(0,0)” encodes \( n = m = 0 \) in the \((neV/h, meV/h)\) labels of the harmonics of the Josephson frequency.

Appendix C: Details on the analytical calculations

Combining the Dyson Eq. (B6) to Eqs. (19)–(20) yields
\[
G_{a,a} = \tilde{g}_{a,a} \tilde{G}_{a,a} \tag{C1}
\]
\[
G_{a,b} = \tilde{g}_{a,b} \tilde{G}_{a,b}. \tag{C2}
\]
The Dyson equations take the form
\[
\hat{G}^{AR} = \hat{g}^{AR} + \hat{g}^{AR} \otimes \hat{f} \otimes \hat{G}^{AR}, \tag{B6}
\]
Then, Eqs. (C1)-(C2) and Eq. (C3) yield
\[ \tilde{G}_{x,x} = \tilde{g}_{x,x} + \tilde{g}_{x,x} R_{x,x} \tilde{G}_{x,x} + \tilde{g}_{x,x} R_{x,x} \tilde{G}_{x',x}, \] (C5)
where
\[ R_{x,x} = \tilde{g}_{x,a} \tilde{g}_{x,a} + \tilde{g}_{x,x} \tilde{g}_{x,x} \tilde{g}_{x,x} \tilde{g}_{x,x} \tilde{g}_{x,x}. \] (C6)

Conversely, Eqs. (C1)-(C2) and Eq. (C4) yield
\[ \tilde{G}_{x,x} = \tilde{g}_{x,x} + \tilde{g}_{x,x} R_{x,x} \tilde{G}_{x,x} + \tilde{g}_{x,x} R_{x,x} \tilde{G}_{x',x}, \] (C8)
where it turns out that \( R_{x,x} = R_{x,x} \) and \( R_{x',x} = R_{x',x} \). Thus, Eqs. (C5) and (C8) are compatible with each other. Given Eq. (B7), Eqs. (B10)-(B13) and Eq. (C1), we obtain
\[ \tilde{G}_{x,x} = \left[ I - \tilde{L}_{x,x} \tilde{K}_{x,x} \tilde{L}_{x',x} \tilde{K}_{x',x} \right]^{-1} \tilde{L}_{x,x}. \] (C17)

The Dyson Eqs. (C3)-(C4) lead to
\[ \tilde{G}_{x,x} = \tilde{g}_{x,x} + \tilde{g}_{x,x} R_{x,x} \tilde{G}_{x,x} + \tilde{g}_{x,x} R_{x,x} \tilde{G}_{x',x}, \] (C15)
\[ \tilde{G}_{x',x} = \tilde{g}_{x',x} \tilde{G}_{x',x} + \tilde{g}_{x',x} \tilde{G}_{x',x} \tilde{G}_{x',x}. \] (C16)
where
\[ \tilde{L}_{x,x} = \left[ \left( \tilde{g}_{x,x} \right)^{-1} - \tilde{K}_{x,x} \right]^{-1} \] (C18)
\[ \tilde{L}_{x',x} = \left[ \left( \tilde{g}_{x',x} \right)^{-1} - \tilde{K}_{x',x} \right]^{-1}. \] (C19)

Then, we deduce Eqs. (21)-(24) in Section IV.
