Regulation of substrate utilization and adiposity by Agrp neurons

João Paulo Cavalcanti-de-Albuquerque\textsuperscript{1,2}, Jeremy Bober\textsuperscript{1}, Marcelo R. Zimmer\textsuperscript{1,3} & Marcelo O. Dietrich\textsuperscript{1,3,4}

The type of nutrient utilized by the organism at any given time—substrate utilization—is a critical component of energy metabolism. The neuronal mechanisms involved in the regulation of substrate utilization in mammals are largely unknown. Here, we found that activation of hypothalamic Agrp neurons rapidly altered whole-body substrate utilization, increasing carbohydrate utilization, while decreasing fat utilization. These metabolic changes occurred even in the absence of caloric ingestion and were coupled to increased lipogenesis. Accordingly, inhibition of fatty acid synthase—a key enzyme that mediates lipogenesis—blunted the effects of Agrp neuron activation on substrate utilization. In pair-fed conditions during positive energy balance, activation of Agrp neurons improved metabolic efficiency, and increased weight gain and adiposity. Conversely, ablation of Agrp neurons impaired fat mass accumulation. These results suggest Agrp neurons regulate substrate utilization, contributing to lipogenesis and fat mass accumulation during positive energy balance.
Obesity is a major health problem that results from altered regulation of energy balance. Energy balance is the relation between energy intake and energy expenditure. When energy balance is positive (intake>expenditure), there is an increase in energy storage and fat accumulation. A chronic state of positive energy balance leads to obesity. However, a less appreciated component in the regulation of energy balance is the selection of the type of substrate—typically carbohydrate versus fat—used in metabolic reactions. This substrate selection (or substrate utilization) is important as different energy substrates yield different amounts of free energy. Impairment in the capacity to shift between different energy substrates is linked to obesity1. Thus, it is important to identify how the organism controls substrate utilization for a better understanding of the regulation of energy balance and obesity development.

Energy metabolism is tightly controlled by the hypothalamus. Agouti-related peptide producing neurons (hereafter, Agrp neurons)2–5 in the hypothalamic regulate energy metabolism by responding to a variety of circulating factors6–9. These neurons are active during food deprivation10–12 and are strongly associated to control of food intake2,5,13–18. However, recent work suggested that Agrp neurons also regulate other metabolic processes, including white adipose tissue (WAT) browning19 and brown adipose tissue glucose metabolism20 and thermogenesis19,21. During our previous studies investigating the function of Agrp neurons14,19,22, we observed rapid changes in whole-body substrate utilization upon activation of Agrp neurons. Based on these unexpected observations, we investigated the involvement of Agrp neurons in the regulation of peripheral substrate utilization and lipogenesis.

Here, we report that Agrp neurons rapidly shift whole-body metabolism towards lipid storage, a mechanism we suggest as being important for fat accumulation during positive energy balance (i.e., a metabolic state coupled to weight gain).

**Results**

**Acute switch in nutrient utilization upon Agrp neuron activation.** To gain insight into the acute regulation of metabolism by Agrp neurons, nutrient utilization was measured by indirect calorimetry upon activation of these neurons. AgrpTrpv1 mice (as previously characterized14,19) were used to specifically activate Agrp neurons by selectively expressing the capsaicin-sensitive channel, Trpv1, which is transiently activated by peripheral injection of capsaicin. Activation of Agrp neurons by capsaicin rapidly increased food intake in AgrpTrpv1 mice (Fig. 1a and Supplementary Figure 1)14. We also observed a sharp increase in respiratory exchange ratio (RER)—calculated as the ratio (VCO2/VO2)—in these animals (Fig. 1b), in line with the observed fast kinetics of feeding, suggesting an acute shift in substrate utilization towards carbohydrates relative to fat. Based on gaseous exchange23, we calculated total rates of fat utilization and carbohydrate utilization for the whole animal. In line with changes in RER, activation of Agrp neurons led to a rapid and prolonged decrease in fat utilization (Fig. 1c) and increase in carbohydrate utilization (Fig. 1d). Because this experiment was performed in the presence of food and the effects on nutrient utilization were prolonged compared to feeding upon Agrp neuron activation (Fig. 1a)14, these metabolic shifts could be due to changes in postprandial metabolism. Using linear regression analysis between the initial bout of food intake (0–30 min) and the subsequent RER (30–60 min), we could not find a positive correlation between these parameters (Fig. 1e). However, the lack of positive correlation could be explained by a ceiling effect.

We did not observe statistically significant changes in VO2 (Fig. 1f), VCO2 (Fig. 1g) or energy expenditure (Fig. 1h). However, non-statistical decreases in VO2 and increases in VCO2 accounted for the changes in RER (inserts Fig. 1f, g). We also measured activity levels upon Agrp neuron activation14 and did not observe statistical changes in ambulatory activity (Fig. 1i). Thus, these results suggest Agrp neurons rapidly control whole-body substrate utilization, an effect that could be the consequence of postprandial metabolic shifts.

**Agrp neuron activation control substrate utilization in the absence of ingestion.** We further explored the extent to which activation of Agrp neurons and carbohydrate ingestion interact to rapidly shift metabolism (Supplementary Figure 2 and Supplementary Note 1). We infused both control and AgrpTrpv1 mice with glucose (2 g·kg⁻¹ body weight, via gavage) and activated Agrp neurons by injecting capsaicin (Fig. 2a). Food was removed from the cage during the experiment to prevent ingestion. Activation of Agrp neurons led to an increased peak and a more sustained elevation of RER (Fig. 2b, c), an effect that was present even in mice that did not receive glucose infusion (Fig. 2b, c). Accordingly, activation of Agrp neurons led to a sustained decrease in fat utilization (Fig. 2d, e) and increase in carbohydrate utilization (Fig. 2f, g), regardless of glucose infusion. These results suggest that activation of Agrp neurons alone is capable of promoting shifts in substrate utilization.

In the previous experiments, even in animals infused with saline via gavage, small amounts of liquid were delivered, raising the possibility that acute gastric distension acts together with Agrp neuron activation to promote changes in substrate utilization. To exclude this possibility, we repeated our experiments in a new cohort of mice in which Agrp neurons were activated in the absence of food (Fig. 3a). In line with our previous findings, activation of Agrp neurons induced an increase in RER (Fig. 3b), a decrease in fat utilization (Fig. 3c) and an increase in carbohydrate utilization (Fig. 3d). In support of these results, activation of Agrp neurons using DREADD (designer receptor exclusively activated by designer drugs) also showed similar shifts in substrate utilization (Supplementary Figure 3 and Supplementary Note 2).

We measured ambulatory activity and found an increase upon activation of Agrp neurons in the absence of food (Fig. 3e), suggestive of foraging behaviors14,16,24. Importantly, activity levels between control and AgrpTrpv1 mice started to diverge around 20–25 min after capsaicin injection, while RER started to diverge around 10–15 min. The fact that RER started to diverge before activity levels suggests that the effect of Agrp neuron activation on RER is independent of an increase in locomotion. To further rule out the effects of activity on RER, we used linear regression analysis (Fig. 3f, g). We found that activity levels and RER were weakly correlated in both control and AgrpTrpv1 mice (control: \( r^2 = 0.244, F_{1,63} = 20.12, P < 10^{-4} \); AgrpTrpv1: \( r^2 = 0.155, F_{1,63} = 11.21, P < 10^{-3} \)). However, the slopes were not statistically different from each other (control: slope = 1.68 × 10⁻⁴ ± 0.37 × 10⁻⁴; AgrpTrpv1: slope = 1.21 × 10⁻⁴ ± 0.36 × 10⁻⁴; \( F_{1,126} = 0.82, P = 0.36 \)), suggesting the physiological relationship between RER and activity levels is not altered by Agrp neuron activation. Importantly, across different activity levels, activation of Agrp neurons increased RER, as evidenced by the parallel linear regression lines and by statistically different intercepts (control: intercept = 0.766 ± 0.005; AgrpTrpv1: intercept = 0.878 ± 0.007, \( F_{1,127} = 201.5, P < 10^{-4} \) (Fig. 3f, g). Thus, these results demonstrate that activation of Agrp neurons increases RER.
Independently of the ingestion of food, an effect that cannot be fully explained by changes in activity levels.

Participation of lipogenesis in Agrp neuron-mediated shifts in metabolism. We next explored biochemical changes in peripheral tissues that could be mechanistically linked to the observed shifts in metabolism upon activation of Agrp neurons. We found that in the absence of food ingestion, Agrp neuron activation decreased circulating levels of non-esterified fatty acids (NEFAs, Fig. 4a, b) with no changes in basal blood glucose levels (Fig. 4c). The lack of changes in basal blood glucose levels do not exclude the possibility that Agrp neurons control glucose handling during glucose challenge. Because circulating NEFAs decrease upon Agrp neuron activation, these results suggest a decrease in release, and possibly an increase in deposition of fat. To test this hypothesis, we measured expression levels of genes involved in lipid metabolism in the WAT from AgrpTrpv1 mice and control mice 60 min after capsaicin injection. We found a decrease in the expression level of Ppara (Fig. 4d), a gene involved in the promotion of fat catabolism. We also found a significant increase in expression levels of hexokinase2 (hk2; Fig. 4d), a rate-limiting enzyme involved in glycolysis, a critical metabolic step to provide carbons for de novo lipogenesis. Hormone-sensitive lipase (HSL) is an essential step in the breakdown of triglycerides to release fatty acids in circulation. Activation of hormone-sensitive lipase occurs by phosphorylation of this enzyme in several serine residues. Upon activation of Agrp neurons, we found decreased levels of phosphorylated hormone-sensitive lipase (p-HSL) in WAT compartments (Fig. 4e and Supplementary Figure 6). Together, these experiments indicate activation of Agrp neurons leads to increased lipogenesis and decreased lipolysis in the WAT.

De novo lipogenesis can drive RER above 1.023, and could be a potential factor involved in Agrp neuron activation-mediated shifts in RER. To test for the participation of fat synthesis in the rapid effects of Agrp neurons on metabolism, we blocked fatty acid synthase (FAS), a key enzyme involved in fat storage. We treated mice with a pharmacological inhibitor of fatty acid synthase (C75, 10 mg kg⁻¹, i.p.) and activated Agrp neurons.
Glucose ingestion and Agrp neurons control substrate utilization independently. a Control and Agrp<sup>Trpv1</sup> mice received a bolus of saline or glucose (2 g kg<sup>−1</sup>) via gavage followed by peripheral injection of capsaicin (10 mg kg<sup>−1</sup>, intraperitoneal (i.p.)). b Respiratory exchange ratio (RER). c Mean RER after gavage (interaction: F<sub>1,40</sub> = 9.82, P = 0.003; gavage solution: F<sub>1,40</sub> = 8.20, P = 0.006; genotype: F<sub>1,40</sub> = 71.31, P < 0.0001). d Fat utilization. e Mean fat utilization after gavage (interaction: F<sub>1,40</sub> = 7.91, P = 0.007; gavage solution: F<sub>1,40</sub> = 6.07, P = 0.01; genotype: F<sub>1,40</sub> = 79.82, P < 0.0001). f Carbohydrate utilization. g Mean carbohydrate utilization after gavage (interaction: F<sub>1,40</sub> = 8.29, P = 0.006; gavage solution: F<sub>1,40</sub> = 5.26, P = 0.02; genotype: F<sub>1,40</sub> = 37.44, P < 0.0001). In c, e and g statistical analysis was performed using two-way analysis of variance (ANOVA) on the mean response after gavage and capsaicin injection; genotype (control vs. Agrp<sup>Trpv1</sup>) and gavage infusion (saline vs. glucose) were used as factors for the ANOVA. Holm-Sidak’s multiple comparisons test (MCT) was used to find post hoc differences among groups. MCTs are indicated as *P < 0.05, **P < 0.01, ***P < 0.001 and ****P < 0.0001 in figure panels. Control mice + saline gavage (n = 11); control mice + glucose gavage (n = 12); Agrp<sup>Trpv1</sup> mice + saline gavage (n = 10); Agrp<sup>Trpv1</sup> mice + glucose gavage (n = 11). Dashed gray line indicates time of oral gavage and capsaicin injection.

in indirect calorimetry chambers (Fig. 4f). Treatment of control mice with the fatty acid synthase inhibitor had no effects on RER (Fig. 4g), fat utilization (Fig. 4j) or carbohydrate utilization (Fig. 4m). The lack of effects of fatty acid synthase inhibition on substrate utilization is in line with the low levels of lipogenesis during the light cycle of mice. In contrast to control animals, inhibition of fatty acid synthase blocked the effects of Agrp neuron activation on substrate utilization (Fig. 4h, i, k, l, n, o). These results provide further support for the rapid shift in metabolism towards lipogenesis mediated by Agrp neuron activation in mice.

Sympathetic signaling mediates peripheral effects of Agrp neurons. Norepinephrine release and binding to adrenergic receptors on fat compartments promotes lipolysis, while its inhibition favors lipogenesis. Accordingly, we predicted that Agrp neurons control substrate utilization and lipogenesis by inhibiting sympathetic signaling on fat compartments in anadibolic state. Here, we treated mice with a β3-adrenergic receptor agonist (CL 316,243)<sup>28</sup> (Fig. 5a), which are highly selective to fat compartments<sup>29</sup>, while activating Agrp neurons (Fig. 5a). Treatment of control mice with CL 316,243 did not alter RER (Figs. 5b and 5d) but prevented the increase in RER upon Agrp neuron activation in Agrp<sup>Trpv1</sup> mice (Fig. 5c-d). When we calculated fat utilization, CL 316,243 completely reverted the inhibition of whole-body fat utilization upon Agrp neuron activation (Fig. 5e, g) but had no effects in control animals (Fig. 5f, g). Concomitantly, CL 316,243 prevented the increase in carbohydrate utilization upon activation of Agrp neurons (Fig. 5h-j). Thus, promotion of β3-adrenergic receptor signaling using a pharmacological agonist reverts the effects of Agrp neuron activation on peripheral fuel metabolism.

Next, we tested whether CL 316,243 could acutely block the effects of Agrp neuron activation on food intake. We first performed a dose response study to detect the range of CL 316,243 doses that could revert the increase in RER upon Agrp neuron activation. We found that doses as low as 0.01 mg kg<sup>−1</sup> almost completely reversed the effects of Agrp neurons on RER (Fig. 5k). Next, we selected two doses of CL 316,243 (1.00 and 0.01 mg kg<sup>−1</sup>) to investigate its effects on food intake mediated by Agrp neuron activation. In all conditions tested, CL 316,243 did not revert the effects of Agrp neuron activation on food intake (Fig. 5l, m). Of note, CL 316,243 is highly anorexigenic<sup>28</sup>, but its effects are observed after several hours and not as rapid as the effects of Agrp neuron activation on feeding<sup>14-16</sup>. These findings suggest a divergence between the feeding and metabolic mechanisms underlying Agrp neuron function and support the argument that Agrp neuron activation favors the storage of fat (lipogenesis) in situations of energy surplus by suppressing sympathetic activity.

Agrp neuron activation potentiates adiposity in obesogenic conditions. Since Agrp neuron activity shifts metabolism toward lipogenesis, it is expected that during prolonged neuronal activation mice will accumulate more fat than control counterparts.
Agrp neuron activation induces a shift in substrate utilization. a Control (black, n = 5) and Agrp\textsuperscript{Trpv1} (blue, n = 5) mice were tested in indirect calorimetry chambers upon injection of capsaicin without food provided. b Respiratory exchange ratio (RER) (interaction: F\textsubscript{12, 96} = 8.96, P < 0.0001; time: F\textsubscript{12, 96} = 1.31, P = 0.22; genotype: F\textsubscript{1, 8} = 54.45, P < 0.0001). c Calculated fat utilization (interaction: F\textsubscript{12, 96} = 3.52, P = 0.0002; time: F\textsubscript{12, 96} = 3.23, P = 0.0006; genotype: F\textsubscript{1, 8} = 55.31, P < 0.0001). d Calculated carbohydrate utilization (interaction: F\textsubscript{12, 96} = 13.52, P < 0.0001; time: F\textsubscript{12, 96} = 6.25, P < 0.0001; genotype: F\textsubscript{1, 8} = 58.16, P < 0.0001). e Ambulatory activity (interaction: F\textsubscript{12, 96} = 1.12, P = 0.34; time: F\textsubscript{12, 96} = 7.13, P < 0.0001; genotype: F\textsubscript{1, 8} = 5.29, P = 0.05). f Linear regression models of activity levels (in arbitrary units) and RER in control (gray) and Agrp\textsuperscript{Trpv1} (red) mice. g Residuals from the linear regression model. In b, c, d and e, statistical analysis was performed using two-way analysis of variance (ANOVA) with time as a repeated measure followed by Holm-Sidak’s multiple comparisons test (MCT; not shown). Dashed line indicates time of capsaicin injection. Symbols indicate mean ± SEM.

To test this assumption, we daily activated Agrp neurons in Agrp\textsuperscript{Trpv1} mice and measured body weight and fat mass changes over 10 days in ad libitum fed animals. Repeated activation of Agrp neurons led to an increase in food intake, body weight gain, fat mass and metabolic efficiency (Supplementary Figure 4), i.e., the amount of body weight gained related to the amount of energy ingested.

To further dissect the discrete contribution of Agrp neurons to adiposity and weight gain during obesogenic conditions, we set out to selectively activate Agrp neurons under controlled positive energy balance. We took advantage of the physiological hyperphagia that occurs when rodents are switched from a normal chow diet to a high-fat diet in the laboratory.\textsuperscript{30,31} In our colony, this acute dietary switch led to an increase of ~86% in the amount of overnight calories consumed (Fig. 6a). Based on these data, we designed a pair-fed study in which control and Agrp\textsuperscript{Trpv1} mice could be fed more calories than they would usually consume under a regular chow diet, thus inducing a state of positive energy balance (Fig. 6b). When control and Agrp\textsuperscript{Trpv1} mice were fed an isocaloric high-fat diet (compared to their ad libitum normal chow intake), activation of Agrp neurons did not lead to changes in body weight gain or metabolic efficiency (Fig. 6c). However, when pair-fed 25% or 50% more calories than their ad libitum food intake under a normal chow diet, activation of Agrp neurons in Agrp\textsuperscript{Trpv1} mice increased body weight gain and metabolic efficiency compared to littermate controls (Fig. 6d, e).

When switched to a high-fat diet, mice displayed hyperphagia lasting 5 days (Fig. 6f).\textsuperscript{30,31} We took advantage of this phenomenon to study mice in positive energy balance in a more prolonged pair-fed experiment (Fig. 6g). Using this approach, we controlled the number of calories ingested by control and Agrp neuron activated mice during 5 days of hyperphagia (Fig. 6h). Despite identical food intake, activation of Agrp neurons increased body weight gain compared to control mice (Fig. 6i).

We then measured the metabolic efficiency and changes in fat mass at the end of the study (day 6) compared to day 0—when we introduced the high-fat diet. In this experimental setting, activation of Agrp neurons increased metabolic efficiency (Fig. 6i) and fat mass gain (Fig. 6k) with no changes in lean mass (delta lean mass: control = 0.26 ± 0.39, n = 8; Agrp\textsuperscript{Trpv1} = 0.24 ± 0.20, n = 8; t\textsubscript{4} = 0.04, P = 0.96, t-test). In support of these findings, we found similar results in Agrp\textsuperscript{hM3Dq} mice (Supplementary Figure 5 and Supplementary Note 3).

Ablation of Agrp neurons impairs adiposity. Finally, we tested whether the loss of function of Agrp neurons would impair adiposity in conditions of positive energy balance. We studied control and Agrp\textsuperscript{DTR} mice,\textsuperscript{17} allowing controlled ablation of these neurons. In adults, ablation of Agrp neurons leads to aphagia and death\textsuperscript{17}. To bypass the aphagia after Agrp neuron ablation, we devised an enteral feeding scheme using a gastrostomy tube to deliver controlled amounts of liquid diet into the stomach of mice (Fig. 7a). After tube implantation, mice were allowed to recover from surgery and acclimate to liquid diet for 2 days. We then started to gradually increase the amount of diet infused in the stomach, until reaching positive energy balance (animals started to gain body weight). At post-surgery days 7 and 9, we injected diphertheria toxin (50 μg kg\textsuperscript{-1}, intramuscular) to ablate Agrp neurons. In this feeding regimen, ablation of Agrp neurons did not lead to death and mice continued to increase body weight (Fig. 7b). However, ablation of Agrp neurons led to a significant decrease in fat mass gain (Fig. 7c) but not lean mass (delta lean mass: control = −0.07 ± 0.30, Agrp\textsuperscript{DTR} = 0.13 ± 0.49; U = 9, P = 0.45, Mann–Whitney test) as measured by repeated magnetic resonance imaging (MRI) scans before the first diphertheria toxin injection and at the end of the study. At 6 days after the first injection of diphertheria toxin, we dissected the fat tissue for...
Fig. 4 Agp neurons promote lipogenesis. **a** Control (black) and Agp\(^{Trpv1}\) (blue) mice were injected with capsaicin. **b** NEFA levels (interaction: \(F_{2,54} = 3.91, P = 0.02\); time: \(F_{2,54} = 9.64, P = 0.0003\); genotype: \(F_{1,27} = 1.74, P = 0.19\); MCT: \(P_{\text{gen} \times \text{m}} = 0.03\)). **c** Blood glucose levels (interaction: \(F_{2,54} = 1.47, P = 0.23\); time: \(F_{2,54} = 14.6, P < 0.0001\); genotype: \(F_{1,27} = 0.67, P = 0.41\); MCT: ns). Control mice + vehicle (n=8); control mice + C75 (n=8); Agp\(^{Trpv1}\) mice + vehicle (n=7); Agp\(^{Trpv1}\) mice + C75 (n=7). Dashed line indicates time of injections. Colored symbols indicate mean ± SEM. Gray symbols indicate individual values.
biochemical analysis and the brain to confirm ablation of Agrp neurons. After diphtheria toxin treatment, only minimal residual Agrp-positive neuronal fibers were visualized in the arcuate nucleus (Fig. 7d), confirming the ablation of Agrp neurons is not affected by enteral feeding. In the WAT, we measure genes involved in lipid metabolism and found decreased expression of several genes involved in lipogenesis (Fig. 7e). Altogether, these results support the idea that Agrp neuron activity mediates weight gain and adiposity in positive energy balance conditions.

**Discussion**

Here, we reported that Agrp neurons shift metabolism towards lipid storage, a mechanism we suggest being important for fat accumulation during positive energy balance (i.e., a metabolic state coupled to weight gain).

During diet-induced obesity, the activity of Agrp neurons is elevated as recorded using slice electrophysiology. This elevated activity of Agrp neurons could be involved in the metabolic shifts towards fat deposition (lipogenesis) reported here. In fact, a recent report showed that activation of Agrp neurons in Agrp hM3Dq mice during 2 weeks by providing clozapine-N-oxide (CNO)—the pharmacological agonist of the excitatory receptor hM3Dq—in the drinking water increased food intake only during the first 2 days. However, mice continued to increase body weight during the entire period of study, suggesting a role for Agrp neurons in body weight gain that was not due to increased feeding. Additionally, mice with impaired activity of Agrp...
neurons during high-fat feeding were resistant to diet-induced obesity with only minor or no effects on food intake. Thus, previous reports and our current findings strongly suggest that persistent elevation of Agrp neuron activity during positive energy balance propagate adiposity.

In the WAT, activation of the sympathetic nervous system leads to lipolysis, whereas its inhibition favors lipogenesis. Direct recordings of sympathetic nerve electrical activity showed that activation of Agrp neurons decreases sympathetic nerve activity in peripheral tissues. Direct recordings of sympathetic nerve electrical activity showed that activation of Agrp neurons decreases sympathetic nerve activity in peripheral tissues. Conversely, inhibition of Agrp neurons increased sympathetic nerve activity in up to 60%. These effects were mediated by projections of Agrp neurons to paraventricular nucleus (PVH) and dorsomedial hypothalamic nucleus. Together with our studies using a pharmacological agonist of β3-adrenergic receptors, these findings support that Agrp neurons control sympathetic nerve activity in the WAT to control lipogenesis and adiposity. As we will discuss below, we speculate that in addition to diet-induced obesity this function of Agrp neurons is important in the daily anticipatory responses to food ingestion.

Agrp neurons release gamma-aminobutyric acid (GABA) and neuropeptide-Y (NPY) in addition to AGRP. In our experiments, we did not identify which of these transmitters is involved in the effects of Agrp neurons on peripheral substrate utilization. However, previous reports showed that infusion of NPY in the rat brain increases RER, an area in which NPY treatment also induces hyperphagia. Because Agrp neurons project to the PVH to promote feeding, it is possible that NPY released from Agrp neurons in the PVH also modulates the observed changes in substrate utilization. In addition to NPY, Agrp neurons also likely regulate lipogenesis via release of both NPY and AGRP.

Contrary to adult ablation of Agrp neurons which leads to aphagia, neonatal ablation of these neurons is compatible with life. In a previous study, Agrp neurons were ablated during the first postnatal week. The authors found that adult mice...
without Agrp neurons showed decreased RER at the beginning of the dark cycle\textsuperscript{57}, a time when Agrp neuron activity is high\textsuperscript{11}. These results suggested that Agrp neurons are important for the increase in RER that occurs at the onset of the dark phase when lipogenesis is turned on and animals enter an anabolic state, in anticipation to food ingestion. In support of this argument, animals trained in a scheduled feeding regimen showed an elevation of NPY levels in anticipation to a meal\textsuperscript{58,59} and NPY signaling promotes lipogenesis\textsuperscript{60}. Additionally, when fed a scheduled feeding regimen, mice with partial ablation of Agrp neurons showed impaired anticipatory activity before food presentation\textsuperscript{61}. Thus, these findings support a function for Agrp neurons in coordinating the daily anticipatory responses to food intake (see also ref. \textsuperscript{42}), including anticipatory substrate utilization switches.

More recently, two additional reports highlighted the involvement of Agrp neurons in peripheral substrate metabolism\textsuperscript{62,63}. These studies reported on the role of carnitine acetyltransferase (Crat) as a critical enzyme in Agrp neurons to control the switch in peripheral energy metabolism during different metabolic states. Mice knockout for Crat selectively in Agrp neurons had impaired metabolic flexibility—the capacity to shift between energy substrates—and were more predisposed to fat accumulation during positive energy balance\textsuperscript{62,63}. However, the authors did not directly assess the activity of Agrp neurons. Based on the experiments reported here, an increase in Agrp neuron activity in Cart knockout Agrp neurons is expected during positive energy balance. Collectively, these recent reports support the importance of Agrp neurons in regulating peripheral substrate utilization and fat accumulation.

In summary, we showed that Agrp neurons in the hypothalamus rapidly control whole-body nutrient utilization by shifting metabolism towards lipogenesis. These findings have implications for our understanding of how neuronal circuits control energy metabolism and, consequently, to our understanding of severe disordered conditions such as obesity.

**Methods**

**Animals.** Mice used in the experiments were 3 to 8 months old from both genders. Agrp\textsuperscript{Trpv1} mice were generated by crossing Agrp\textsuperscript{Cre} to Rosa26\textsuperscript{LSL-Trpv1} mice backcrossed to a Tprv1\textsuperscript{KO} background to prevent capsaicin action on other cell types.
types. As a result, AgprTrpv1 mice selectively expressed the capsaicin-sensitive channel, Trpv1, in Agpr neurons. Because capsaicin is a highly specific ligand of Trpv1, this expression of capsaicin-sensitive channel was both rapid (latency to start is ~2 min) and short lived (last <1 h), unlike the effects of activating Agpr neurons via the designer receptor hM3Dq. More specifically, AgprTrpv1 mice were: Agpr2fl/−;Trpv1XKO;R26-LSL-Trpv1;AgprTrpv1 mice injected with vehicle (3.3% Tween-80 in saline) or Trpv1XKO;R26-LSL-Trpv1;AgprTrpv1 mice injected with capsaicin. In the experiments reported, all mice were littermates (Agpr neuron activated and controls). We did not observe any differences between the two control groups (in feeding behavior and caloriometry measurements). Therefore, throughout the study we referred to both groups as “controls.” We have carefully characterized this animal model elsewhere. Briefly, to control for ectopic expression of Cre outside Agpr neurons, we have genotyped all our animals to the excised conditional allele and found only rare (~1%) occurrence of ectopic expression of Rosa26R-Cre/L10 mice. With ectopic expression of the conditional allele were excluded from our studies.

We have performed dose–response curves for capsaicin and identified the dose of 10 mg kg⁻¹ (intraperitoneal (i.p.)) as optimal to induce feeding behavior in AgprTrpv1 mice. We have also performed a dose response of capsaicin and measured changes in RER (1, 3, 10 and 30 mg kg⁻¹ i.p.; experiments not reported). We found that 10 mg kg⁻¹ was also the optimal dose to promote changes in RER. Thus, we used only this dose of capsaicin for all the following studies.

Intragastric surgery. The 8–10-week-old singly housed AgprDTR/+ and AgprCre/+ mice were used. At 30 min prior to the first injection, animals were administered a subcutaneous injection of the analgesic buprenorphine (0.1 mg kg⁻¹). Inhalation anesthesia was initiated in an induction chamber via an isoflurane vaporizer. After being deeply anesthetized, animals were immediately laid on a heated mat and a nosecone delivering 2 % isoflurane was placed over the nose of the animal to provide continuous plane of anesthesia throughout the procedure. The dorsal neck and abdomen were shaved and then cleaned with alternating scrubs of 70% ethanol and betadine. A dorsal midline skin incision was made on the neck of the animal and the skin immediately surrounding the incision was separated from the muscle with scissors. Also, a subcutaneous tunnel was opened by extending this separation around the right flank. Following this step, the right jugular vein and appropriate anterior midline abdominal incision was made in the skin and scissors were used to separate the skin from the muscle surrounding the incision and to the right side of the animal. A 1.5 cm incision was then made in the linea alba to allow access to the abdominal cavity. The stomach was gently maneuvered, with sterile cotton swabs saturated with saline, to give specific access to the forestomach. A small triangular pattern of 3 stitches was made with 4-0 silk sutures in the forestomach leaving loose ends of the suture to allow for cinching after insertion of the infusion tube. A 13 cm piece of Micro-Renathene tubing (Braintree Scientific, MR665, 0.065” OD × 0.030” ID) was previously prepared by quickly exposing the tip to a flame to round the edge and provide a subtle fit. A 1 cm labelled end was cut off. A sterile syringe containing saline was used. A 20 G sterile needle, the stomach was carefully punctured in the center of the triangular stitch and the flanged end of the tube was inserted. The silk suture was then cinched closed and tied. The tubing was gently pulled to vent any attachment to the stomach and then the saline was infused into the tube with a 5 mL syringe and a leak free connection. Prior to any subsequent removal of the syringe attached side of the tubing, the tubing was clamped with a soft hemostat to prevent any leakage from the stomach. To route the tube through the peritoneum, a sharp forceps was used to puncture the right exterior side of the peritoneum and the tube was inserted over the tip and pulled through the hole. Then, allowing an air pocket between the peritoneum and the stomach, the tube was pulled through the abdominal wall using 4-0 silk. This prevents slippage of the tubing during normal movement. The abdominal wall was then closed with 4-0 absorbable Vicryl sutures in a continuous pattern. The animal was laid on its side and a trochar was inserted through the skin on the neck and routed dorsally and then laterally until it could be visualized close to the site of the tube. The tube was then inserted into the trochar and pulled through the incision on the back of the neck. The abdominal skin was closed with 5-0 Monofilament sutures. A sterile polyester felt button, 0.563 in. (14 mm) diameter (Intech, cat. no. D56FS) was moistened with saline and inserted over the tubing and placed under the skin on the interscapular region of the animal. This procedure allows for secure externalization of the tubing while preventing stress to the skin. The skin was then closed over the button with 5-0 monofilament sutures and a small droplet of tissue adhesive was used to secure the tube to the plastic exit hole on the felt button. The tube was cut 12 mm above the button and a 5 mm blunt and crimped section of an 18 G needle was inserted into the button to prevent the tubing from being pushed up the tube. Animals were then given a subcutaneous injection of sterile saline and allowed to recover from anesthesia on a heated pad, then returned to their homecage. As a post-operative analgesic, buprenorphine (0.1 mg kg⁻¹) was administered every 6–12 h after surgery for a total of 48 h.

Intragastric diet infusion. Immediately after returning to the homecage, mice were provided with ad libitum access to water, normal chow (Envirodine, Teklad 2185), and a nutritionally assessed AIN-76 liquid diet (Bio-Serv, cat. no. F1268; composition, 180 kcal L⁻¹; fat, 125 kcal L⁻¹; carbohydrate, 695 kcal L⁻¹; total of 1 kcal mL⁻¹). Liquid diet, supplied as a powdered, was mixed fresh daily according to the manufacturer’s specifications. After passing through a mesh filter, liquid diet was provided to mice in 50 mL glass feeding tubes (Bio-Serv cat. no. FI5001) with a stainless-steel nosecone delivering 2 % iso-octane. At days 1–4, 12-GG, 0.065” ID tubing was placed into the stomach after exposure to cervical dislocation with a slight incision, the bregma and lambda points were identified and the head was leveled in an anterior–posterior fashion by adjusting these two points to the same z-depth. Lateral leveling was performed by choosing a point at a fixed lateral distance from bregma and the head was adjusted to match the z-depth on each side. Two small holes were drilled in the skull above the points of injection using a 0.9 mm diameter carbon steel burr attached to a high speed stereotaxic drill (Kopf Model #1474). The accurate nucleus of the hypothalamus was targeted utilizing the following coordinates with bregma as the reference point: anterior/posterior: −1.4 mm, lateral: ± 0.3 mm, dorsal/ventral: −5.9 mm. The virus rAV5H-syn-DIO-hM3Dq (PhD020000) was injected into the side of the head. At 2 days post surgery, normal chow was removed, and mice were connected to a 1.5 m length of Micro-Renathene tubing attached to syringes containing liquid diet. Syringes were mounted in a syringe pump (Harvard Apparatus, model PHD2000) and diet was infused at the following volumes: day 2: 8 mL at 0.4 mL h⁻¹; days 3–10: 10 mL at 0.46 mL h⁻¹; days 11–14: 12 mL at 0.59 mL h⁻¹; days 15–19: 14 mL at 1.48 mL h⁻¹; days 20–24: 16 mL at 1.94 mL h⁻¹; days 25–28: 18 mL at 2.4 h⁻¹. The 1.5 m tube was detached, and animals were administered 0.1 mL of saline through the catheter in order to flush the line and keep it clean. On post-operative days 7 and 9, mice were administered a 50 µg kg⁻¹ intramuscular injection of diphtheria toxin. On days 7 and 13 postoperatively, mice were assessed for body composition by an Echo-MRI 100H analyzer. Animals were killed on day 14 for tissue collection.

Metabolic assays and biochemical analysis. Blood samples were collected from the tail in order to measure glucose and free fatty acids (NEFA) levels. Glucose was measured using a One Touch Ultra 2 glucometer. After blood centrifugation,
serum was collected and used to measure NEFA as indicated by the manufacturer (WAKO, Japan). Body composition was assessed using an Echo-MRI system. Fat gain was measured by the delta between the last and the first MRI scan.

Gene expression and western blotting. Animals were deeply anesthetized with ketamine and xylazine and killed by decapitation. Tissues were collected and frozen in liquid nitrogen. Tissues were lysed in buffer containing 1% Nonidet P-40, 50 mM Tris 3 HCl, 0.1 mM EDTA, 150 mM NaCl, protease inhibitors and protein phosphatase inhibitors. Equal amounts of protein lysate were electrophoresed on sodium dodecyl sulfate–polyacrylamide gel electrophoresis and transferred to polyvinylidene difluoride membranes. Primary antibodies (Lipopolysaccharide Activation Antibody Sampler Kit #8334, Cell Signaling) were incubated at 4 °C overnight at a 1:1000 dilution. Membranes were washed and incubated with secondary antibodies conjugated to horseradish peroxidase. Protein levels were visualized using ECL chemiluminescence substrate and quantified using ImageJ.

Total RNA was extracted from mouse tissues using RNeasy® lipid mini kit (Qiagen). Complementary DNA was reverse transcribed (Bio-Rad) and amplified with SYBR Green Supermix (Bio-Rad) using a Light Cycler 480 real-time PCR system (Roche). Data were normalized to the expression of Actb and Gusb.

The following primers were used: ddx6 (F-GGGCAATGTTAATAGTGCCAAC; R-CCCTGAAATTCAGGAGAAGA); foxo1 (F-AGTTCGGGAACAAGACGTTG; R-CAGTGGGGAGAGAGGACAGA); hsl (F-CTGGGAAGGGCTTTCTGGTT; R-AGGAGAGTGCCAGGAGAAGA); actb (F-TGTGCTATCGCCGAAAGGA; R-GGCTGCTTCAGCTTGGT); pparg (F-GTACGCTGCTGCCTCCAGAGC; R-GGAGAGAGTCTGCAGGAACG); slc2a4 (F-GCGAGGACAGGCTGTAGATG; R-GAATTTCATCAGAGAGCCGC); gusb (F-GTACGCTGCTGCCTCCAGAGC; R-GGCTGCTTCAGCTTGGT); srebp1 (F-AGTTCGGGAACAAGACGTTG; R-CAGTGGGGAGAGAGGACAGA); cd36 (F-TTCACTTTTCTGGGACTGAGAATG; R-GGAGAGAGTCTGCAGGAACG).

Indirect calorimetry and nutrient utilization. Nutrient utilization can be measured by indirect calorimetry, where the measurements of VCO2 production and VO2 consumption are used to calculate the RER 23. Under normal conditions, a RER approaching 0.7 indicates predominant fat oxidation, while a RER approaching 1.0 indicates predominant carbohydrate oxidation 24. Oxygen consumption (VO2) and CO2 production (VCO2) were measured in four to eight mice simultaneously in indirect calorimetry chambers (TSE Systems, Germany). Measurements were recorded every 8–12 min over the entire course of the experiment (except for the experiment reported in Fig. 1 and Supplementary Figure 1, in which measurements were recorded every 30 min). RER was calculated as the area between VCO2 and VO2. Whole-body fat utilization was calculated using the following equation: 1.67 × (VO2 − VCO2). Whole-body carbohydrate utilization was calculated using the following equation: 4.55 × VCO2 – 3.21 × VO2. In these equations, VO2 and VCO2 were in L min−1 and constants are in L g−1 (representing the amount of gas production or consumption in liters per gram of substrate oxidized).

The calculate substrate utilization rate (in g min−1) was converted to mg min−1 for better visualization. All animals were single housed during the experiments in calorimetry chambers. Mice were acclimated to the chambers for several days until they displayed normal circadian variance in metabolic measurements (as reported in Supplementary Figure 1). Typically, this acclimation period lasts ~5–7 days in our laboratory. We also acclimated animals to mock injections to minimize stress response. In all experiments, animals were injected 3–4 times with vehicle in consecutive days (Supplementary Figure 1).

For the glucose response study, mice were provided with glucose (D-Glucose, G8270, Sigma, USA) via gavage. We used saline as vehicle and three doses of glucose (1, 2, and 3 g kg−1 body weight, via gavage feeding). Food was removed 2 h before the experiment due to the light cycle of the animals. Indirect calorimetry was recorded for 60 min prior injection of capsaicin and diet switch. For the experiments where no food was provided, food was removed from the cages 2 h before injecting mice with capsaicin/vehicle. Baseline indirect calorimetry was recorded for 60 min, and then the effects of AgRP neuron activation were recorded for additional 60–120 min. Similar procedures were used in the experiments using hM3Dq to activate AgRP neurons and in the experiments in which compounds were given to mice prior the experiment. Glucose (2 g kg−1, via gavage), C75 (10 mg kg−1, i.p.) or Cl. 316,243 (0.01-1.00 mg kg−1, i.p.) were given together with capsaicin. In all cases, the drugs were injected immediately before capsaicin use with two different syringes.

Statistical considerations. Matlab R2016a, PASW Statistics 18.0, Prism 7.0 and Adobe Illustrator CS6/CC were used to analyze data and plot figures. Student’s t-test was used to compare two groups. Analysis of variance (ANOVA) was used to compare multiple groups. When necessary, multiple comparisons post hoc test (MCT) was used (Holm-Sidak’s test). When homogeneity was not assumed, the Kruskal–Wallis non-parametric ANOVA was selected for multiple statistical comparisons. The Mann–Whitney U test was used to determine significance between groups. Statistical data are provided in the figures. P < 0.05 was considered statistically significant.

Immunohistochemistry. Mice were deeply anesthetized by isoflurane inhalation and killed by decapitation. Brains were immersion fixed in 4% paraformaldehyde for 48 h at 4 °C. Next, coronal brain sections of the arcuate nucleus were cut at thickness of 50 µm on a vibrating blade microtome (Leica VT1000S) and free-floating tissue sections were washed in phosphate-buffer saline (PBS, pH 7.4). Sections were incubated in 0.3% Triton X-100 in PBS for 30 min at room temperature. Tissue sections were next washed 5 times for 5 min in PBS and finally mounted and coverslipped with ProLong Gold Antifade Reagent (Invitrogen) for better visualization. All animals were single housed during the experiments in Supplementary Figure 1. Typically, this acclimation period lasts ~5–7 days in our laboratory. We also acclimated animals to mock injections to minimize stress response. In all experiments, animals were injected 3–4 times with vehicle in consecutive days (Supplementary Figure 1).

For the glucose response study, mice were provided with glucose (D-Glucose, G8270, Sigma, USA) via gavage. We used saline as vehicle and three doses of glucose (1, 2, and 3 g kg−1 body weight, via gavage feeding). Food was removed 2 h before the experiment due to the light cycle of the animals. Indirect calorimetry was recorded for 60 min prior injection of capsaicin and diet switch. For the experiments where no food was provided, food was removed from the cages 2 h before injecting mice with capsaicin/vehicle. Baseline indirect calorimetry was recorded for 60 min, and then the effects of AgRP neuron activation were recorded for additional 60–120 min. Similar procedures were used in the experiments using hM3Dq to activate AgRP neurons and in the experiments in which compounds were given to mice prior the experiment. Glucose (2 g kg−1, via gavage), C75 (10 mg kg−1, i.p.) or Cl. 316,243 (0.01-1.00 mg kg−1, i.p.) were given together with capsaicin. In all cases, the drugs were injected immediately before capsaicin use with two different syringes.

Data availability. The data that support the findings of this study are available in the Nature Research Reporting Summary linked to this article.
