Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
Severe acute respiratory syndrome coronavirus E protein transports calcium ions and activates the NLRP3 inflammasome

ABSTRACT

Severe acute respiratory syndrome coronavirus (SARS-CoV) envelope (E) protein is a viroporin involved in virulence. E protein ion channel (IC) activity is specifically correlated with enhanced pulmonary damage, edema accumulation and death. IL-1β driven proinflammation is associated with those pathological signatures, however its link to IC activity remains unknown. In this report, we demonstrate that SARS-CoV E protein forms protein–lipid channels in ERGIC/Golgi membranes that are permeable to calcium ions, a highly relevant feature never reported before. Calcium ions together with pH modulated E protein pore charge and selectivity. Interestingly, E protein IC activity boosted the activation of the NLRP3 inflammasome, leading to IL-1β overproduction. Calcium transport through the E protein IC was the main trigger of this process. These findings strikingly link SARS-CoV E protein IC induced ionic disturbances at the cell level to immunopathological consequences and disease worsening in the infected organism.

Introduction

Coronaviruses (CoVs) cause respiratory diseases in humans ranging from common colds to fatal pneumonias (Graham et al., 2013; Perlman and Netland, 2009). At the end of 2002, the etiological agent of severe acute respiratory syndrome (SARS-CoV) emerged in Guandong province, Southeast China, initiating a global epidemic. Approximately 8000 people were infected by the virus, whose severe disease resulted in a 10% mortality rate (Drosten et al., 2003; Rota et al., 2003). The SARS-CoV epidemic was controlled by the summer of 2003, and the virus has not naturally reemerged since (http://www.who.int). However, CoVs similar to those causing SARS, MERS, and many other human and animal diseases have been detected in bat species circulating all over the globe (Annan et al., 2013; Muller et al., 2007; Quan et al., 2010). Bats are now considered the natural host for most CoVs, providing a perfect scenario for recombination events among different viral species leading to the emergence of new viruses, able to cross species barriers and cause devastating illness in other animals and humans (Graham et al., 2013). For this reason, development and implementation of broad spectrum treatments and general therapeutic strategies against CoVs are a high priority.

CoVs are enveloped viruses containing the largest positive-sense RNA genomes known, around 30 Kb, which encode the viral replicase and a set of structural proteins: spike (S), envelope (E) and membrane (M), present in the viral envelope, and nucleocapsid (N) located inside the viral particle (Enjuanes et al., 2008). The S protein interacts with the cellular receptor to trigger viral entry into the host cell (Enjuanes et al., 2008; Wong et al., 2004). The E and M proteins actively
participate in viral morphogenesis (de Haan et al., 1999; Lim and Liu, 2001; Nguyen and Hogue, 1997; Ruch and Machamer, 2012), and the N protein coats the viral genome to form a helicoidal nucleocapsid that remains protected within the viral envelope (Narayanan et al., 2000). Depending on the CoV species, there are other accessory proteins, some structural, that are also encoded by the genome. SARS-CoV encodes the highest number of accessory genes (3a, 6, 7a 7b, 8a, 8b and 9b), which play diverse roles eventually related to pathogenesis (Enjuanes et al., 2008).

To analyze the mechanisms leading to the high virulence of SARS-CoV and MERS-CoV, several mutants affecting their different genes have been generated (Almazan et al., 2013; DeDiego et al., 2007; DeDiego et al., 2014a; Scobey et al., 2013; Yount et al., 2005). Remarkably, deletion of SARS-CoV E gene produced a virus that was attenuated in at least three different animal models and conferred protection against SARS-CoV challenge (DeDiego et al., 2007, 2008, 2011; Fett et al., 2013; lamirande et al., 2008; Netland et al., 2010). Small deletions in different domains of the E protein caused similarly attenuated viruses, and are promising vaccine candidates (Regla-Nava et al., 2015). In a similar approach, a MERS-CoV missing the E gene was generated, resulting in a replication-competent, propagation-defective virus which may also constitute the basis of a safe attenuated vaccine (Almazan et al., 2013).

The CoV E gene encodes a small transmembrane protein highly synthesized during infection (Maeda et al., 2001; Nieto-Torres et al., 2011; Raamsman et al., 2000) that mainly localizes to the Golgi apparatus and the endoplasmic reticulum Golgi apparatus intermediate compartment (ERGIC), where it facilitates virus production and morphogenesis (Cohen et al., 2011; Corse and Machamer, 2002; Maeda et al., 2001; Na et al., 2005; Venkatagopalan et al., 2015). Notably, when the E protein is present, SARS-CoV overstimulates the NF-κB inflammatory pathway (DeDiego et al., 2014b) and, through its PDZ-binding motif, interacts with the cellular protein syntelin, triggering p38 MAPK activation (Jimenez-Guardado et al., 2014). These signaling cascades result in exacerbated inflammation and immunopathology. The connection between the E protein and virulence has further encouraged the search for other E protein functions that may trigger disease worsening.

One of the most striking functions displayed by the CoV E protein is ion channel (IC) activity. The CoV E protein self-assembles in membranes forming pentameric protein-pimple pores that allow ion transport (Pervushin et al., 2009; Torres et al., 2007; Verdia-Bauguena et al., 2012; Wilson et al., 2004, 2006). Interestingly, lipid head-groups are integral components of the pore and regulate ion conductance and selectivity (Verdia-Bauguena et al., 2012, 2013; ). The SARS-CoV E protein showed a mild preference for cations (Na+, K+) over anions (Cl−) when reconstituted in membranes mimicking the charge and composition of those of the ERGIC/Golgi. In this scenario, the E protein IC showed no selectivity for any particular cation (Verdia-Bauguena et al., 2012), though the relevance and consequences of these IC properties in a cellular context remains unknown.

Alteration of ion, and specially, Ca2+ homeostasis in favor of infection has been already demonstrated in several viral systems. To that end a wide range of viruses encode ion conductive proteins similar to E protein, named viroporins (Nieva et al., 2012). Highly pathogenic RNA viruses such as human immunodeficiency virus-1 (HIV-1), hepatitis C virus (HCV), influenza A virus (IAV), picornaviruses and CoVs, encode one or more of these proteins (Nieva et al., 2012). Viroporins participate in several steps of the life cycle and are usually linked with pathogenesis. Whether IC properties could promote pathways leading to disease worsening has been unknown for a long time. Recently, it was described that point mutations that specifically inhibited SARS-CoV E protein IC activity caused attenuation (Nieto-Torres et al., 2014). Mice infected with E protein IC proficient viruses presented extensive disruption of the pulmonary epithelia and edema accumulation (Nieto-Torres et al., 2014). Edema is the major determinant of acute respiratory distress syndrome (ARDS), the pathology induced by SARS-CoV, leading to death (Graham et al., 2013; Hollenhorst et al., 2011; Matthy and Zemans, 2011). Edema and an IL-1β mediated proinflammatory response was increased in the lung parenchyma when E protein IC activity was present (Nieto-Torres et al., 2014).

IL-1β is a potent proinflammatory cytokine crucial in resolving infectious processes; however, its overproduction has been correlated with diverse severe inflammatory diseases such as asthma, ARDS, gout, atherosclerosis and Parkinson’s (Dinarello, 2009; dos Santos et al., 2012; Martinon et al., 2006; Pugin et al., 1996; Strowig et al., 2012). Organisms tightly control IL-1β production through macro-molecular complexes called inflammasomes, which are mainly expressed in macrophages and dendritic cells although other cell types, such as those of the bronchiolar epithelium, synthesize their components (Ichinohe et al., 2010; Triantafillou and Triantafillou, 2014). One highly studied inflammasome is the nucleotide-binding oligomerization domain (NOD)-like receptor pyrin domain-containing protein 3 (NLRP3) inflammasome, relevant in the pulmonary tissue. This complex is composed of the sensing receptor NLRP3, the adapter component apoptosis-associated speck-like protein containing a caspase activation and recruitment domain (ASC) and the catalytically inactive procaspase-1 (Elliott and Sutterwala, 2015; Latz et al., 2013). The inflammasome components are synthesized under precise danger stimuli, such as molecular patterns associated to infections. However, a second signal is sequentially needed to induce their assembly, which triggers the inflammasome. This leads to the processing of procaspase-1 into active caspase-1, which cleaves inactive pro-IL-1β into its mature form IL-1β that is released to the extracellular media to stimulate proinflammation (Elliott and Sutterwala, 2015; Latz et al., 2013). The presence of ionic imbalances within cells is a main trigger of the NLRP3 inflammasome assembly and activation (Latz et al., 2013). Interestingly, several viroporins stimulate this pathway through alteration of cell ion homeostasis, frequently involving Ca2+ imbalances (Ichinohe et al., 2010; Ito et al., 2012; Triantafillou et al., 2013a; Triantafillou and Triantafillou, 2014).

There is clear evidence correlating NLRP3 inflammasomes and IL-1β driven proinflammatory cascades with worsening of several respiratory diseases, including those caused by viruses (dos Santos et al., 2012; McAuley et al., 2013; Pugin et al., 1996; Triantafillou and Triantafillou, 2014). However, the specific role that viral proteins with IC activity may play in this process has not been fully determined. Overproduction of IL-1β in the airways of the lungs of mice infected with E protein IC proficient SARS-CoVs, strongly suggested that ion conductivity may be stimulating the inflammasome (Nieto-Torres et al., 2014). Here we demonstrate that SARS-CoV E protein forms a Ca2+ permeable channel in ERGIC/Golgi membranes. E protein IC activity alters Ca2+ homeostasis within cells boosting the activation of the NLRP3 inflammasome, which leads to the overproduction of IL-1β. This data supports that SARS-CoV E protein Ca2+ channel activity may play a role in disease, through overstimulation of inflammasomes leading to immunopathology. Pharmacological inhibition of this pathway may constitute the basis for combined therapeutics applicable for SARS-CoV and other viruses.

### Results

**The SARS-CoV E protein forms Ca2+ permeable ion channels**

Previously, we reported that the SARS-CoV E protein forms channels that are moderately selective for cations in membranes mimicking the ERGIC/Golgi (Verdia-Bauguena et al., , 2012, 2013). Within cells, the movement of different cations through the E protein
pore should be dictated by their respective gradients. Ca\(^{2+}\) possesses the highest asymmetrical distribution between the ER-Golgi lumen (hundred \(\mu\)M) and the cytoplasm (around 100 nM) (Zhou et al., 2009), which should allow the flow of this cation through the E protein IC channel if it is permeable. To test whether this is the case, E protein ICs were first reconstituted in artificial neutral lipid membranes in order to exclude any effect coming from the lipid charge, using 100 mM CaCl\(_2\) solutions. Current jumps corresponding to the assembly of channels in the lipid membrane were detected (Fig. 1A). The most frequent current jump, representing the insertion of a single E protein IC in the lipid membrane, displayed an intensity of 7.2 ± 2.4 pA. Interestingly, values multiple of 7.2 pA were also detected, corresponding to the insertion of two (14.4 pA) or three channels (21.6 pA), reinforcing the previous observation (Fig. 1A and B). Because lipid charge can affect channel conductance (Verdia-Baguena et al., 2012, 2013), single channel conductance was analyzed in ERGIC/Golgi-like membranes that contained approximately 20% negatively charged lipids. Interestingly, the E protein IC showed a slightly higher unitary current jump of 11 ± 4 pA under these conditions, and multiples of this value, evidencing the insertion of additional channels, were also detected (Figs. 1C and D). The presence of the negatively charged lipid head-groups in the channel pore may facilitate Ca\(^{2+}\) flow through the pore.

Fig. 1. SARS-CoV E protein IC activity in CaCl\(_2\) solutions. (A) Current recordings showing intensity jumps (measured in pA) corresponding to the assembly and disassembly of one or several channels in neutral DPhPC membranes. (B) Histogram representing the intensity of the different current jumps recorded and their respective frequency in neutral membranes. Conductance (G), which is the ratio between current intensity and the applied voltage, is also indicated (measured in pS). Current jumps (C) and their corresponding histogram (D) measured in ERGIC/Golgi membranes. (E) Single-channel conductance variation in solutions containing increasing concentrations of CaCl\(_2\). Magenta circles represent data from neutral membranes and blue circles values from ERGIC/Golgi membranes. Error bars show standard deviations from three independent experiments.
channel enhancing current intensity under these conditions. This effect was already reported for E protein and monovalent cations (Verdia-Baguena et al., 2012).

Additional measurements were performed in aqueous solutions with decreasing CaCl₂ concentrations, to approach Ca²⁺ amounts found in the ERGIC/Golgi lumen. IC conductance (G), which is the ratio between the current intensity and the applied voltage, was calculated. Single channel conductance scaled almost linearly with CaCl₂ concentrations in neutral membranes (Fig. 1E). This reflects that ion conduction inside the E protein IC is similar to the conduction of the solution, which increases as the electrolyte concentration rises. These data indicate that the interaction between the channel and the permeating ions is weak, and are in accordance with E protein forming a neutral pore in these conditions, as previously reported for monovalent cation salts (Verdia-Baguena et al., 2013). In ERGIC/Golgi membranes two different regimes depending on the range of CaCl₂ concentrations were observed. A linear relation between conductance and CaCl₂ concentration was again detected in high concentrated solutions. However, IC conductance in ERGIC/Golgi membranes was independent of CaCl₂ concentration in low concentration solutions (below 0.2 M), and higher than in neutral membranes (Fig. 1E). This result suggests that E protein acts as a charged protein–lipid pore in ERGIC/Golgi membranes. In this scenario, the conductance is regulated by the balance between the ions that flow into the channel to neutralize the excess of negative charges and the bulk electrolyte concentration. Collectively, these data indicate that the E protein forms channels that are highly conductive in CaCl₂.

Furthermore, E protein ICs worked very efficiently when reconstituted in ERGIC/Golgi membranes under Ca²⁺ concentrations approaching those found in the lumen of the organelles (hundred μM).

To specifically test E protein selectivity for Ca²⁺, i.e. the ability of the IC to select Ca²⁺ either by its charge or by its intrinsic properties, reversal potential (Erev) experiments were performed. The rational of these experiments is provided next. ICs were reconstituted in lipid membranes that separated two solutions, one with high and the other with low CaCl₂ concentration. This concentration gradient induces the movement of ions through the channel to equilibrate their asymmetric distribution. The potential applied across the channel, which is required to counteract this ion movement leading to zero electric current is the Erev. The Erev can be transformed into channel permeability for Ca²⁺ (PCa²⁺) and Cl⁻ (PCl⁻) by using the Goldman–Hodgkin–Katz equation (Hodgkin and Katz, 1949). To test whether lipid charge may have an effect on E protein, selectivity measurements were performed in neutral, ERGIC/Golgi similar charged membranes, and fully negative-charged membranes. The E protein IC showed PCa²⁺/PCl⁻ values of 0.2 (1/5) in neutral membranes. The value of this permeability ratio is barely the same expected for a non-selective neutral pore just reflecting the different diffusivities of Ca²⁺ and Cl⁻. Therefore, E protein channel is equally selective for Cl⁻ and Ca²⁺ in neutral membranes. Interestingly, the ratio PCa²⁺/PCl⁻ increased when the E protein IC was assembled in membranes containing negatively charged lipids, being 0.5 in ERGIC/Golgi membranes and 1.8 in negative membranes (Fig. 2). These data indicated that lipid charge largely influenced the channel preference for Ca²⁺ showing that under conditions mimicking the ERGIC/Golgi environment, E protein displayed a mild selectivity for Ca²⁺.

Calcium cations and pH modulate E protein channel selectivity

Multivalent ions, such as Ca²⁺, can modulate ion transport across ICs by interacting with the internal charges of their pores (Alcaraz et al., 2009; Garcia-Gimenez et al., 2012; Queralt-Martín et al., 2011). Therefore we tested whether E protein ion selectivity could be modified by the presence of a range of small CaCl₂ concentrations. Ion selectivity was measured using a ten-fold concentration gradient of KCl at pH 6 upon symmetrical addition of very small CaCl₂ concentrations (mM range), at both sides of the membrane. By applying the Erev, the flow of K⁺ and Cl⁻ ions

![Fig. 2. Ca²⁺ selectivity of SARS-CoV E protein channel. Dotted line represents the permeability ratio value for a hypothetical neutral pore. Values above the line represent cation selectivity, and those below correspond to anion selectivity. Error bars show standard deviations.](Image)

![Fig. 3. Modulation of SARS-CoV E protein channel selectivity by Ca²⁺. (A) Reversal potential (Erev) was measured in asymmetric (500 mM ± 50 mM) KCl solutions upon addition of millimolar CaCl₂ concentrations. Two series of experiments were performed: in neutral DPhPC (magenta circles) and negatively charged DPhPS membranes (green squares). Dotted line shows Erev value corresponding to a non-selective ion channel. (B) Effect of pH on E protein Erev measured under the same KCl conditions above mentioned in neutral (magenta circles) and negatively charged membranes in the absence (green squares) or the presence of 15 mM CaCl₂ (orange squares). Dotted line shows the Erev value corresponding to a non-selective ion channel. Error bars represent standard deviations from three independent experiments.](Image)
down their electrochemical potential gradient is prevented. Therefore, Erev measures the relative preference of the channel for K⁺ cations over Cl⁻ anions, but not for Ca²⁺, because calcium concentrations are the same at both sides of the pore. To analyze the relevance of Ca²⁺ on IC selectivity, this type of experiments were performed in neutral and in negatively-charged membranes (Fig. 3A). In charged membranes the addition of small amounts of Ca²⁺ induced significant changes in the channel Erev, whereas in neutral membranes the effect was very small, although still measurable. These results indicate that Ca²⁺ interaction with E protein channel, modifying the effective pore charge, mainly occur with the lipid charges that line the pore, rather than with acidic residues of E protein TM domain.

Previously we reported that pH also modulates E protein channel selectivity by protonation and deprotonation of the titratable residues present in the pore (Verdia-Baguaena et al., 2013). The effect of Ca²⁺ and pH on E protein selectivity was simultaneously tested. Erev titration was studied in the presence or absence of 15 mM CaCl₂ under different pH conditions (Fig. 3B). In negatively-charged lipid membranes, rising pH induced sequential deprotonation of lipid head-groups and E protein glutamic acid residues as their respective pKa, (1.73 for lipid head-groups and 4.5 for glutamic acid) were overtaken, conferring an excess of negative charges to the channel and making it cation selective. The addition of Ca²⁺ when E protein is reconstituted in charged membranes reduces the cationic selectivity or increases the anionic selectivity (i.e., it shifts the reversal potential towards less negative values), and reversal potential values become closer to those obtained in neutral membranes. This indicates that Ca²⁺ ions interact with the acidic protein residues and the negative lipid head-groups and decrease the effective negative charge of the E protein pore. This effect was especially patent at physiological values of pH (pH 6–7.5). In addition, this interaction of Ca²⁺ ions with the protein acidic residues shifts their effective pKa towards lower values. These results indicate that both Ca²⁺ and H⁺ ions change E channel transport properties by modifying the charge of the pore, and further support that Ca²⁺ enters within E protein IC.

Identification of SARS-CoV E protein ion channel mutants lacking Ca²⁺ transport

In order to assess the biological impact of SARS-CoV E protein with and without Ca²⁺ channel activity, we evaluated previously constructed mutants containing amino acids substitutions known to affect the E protein IC. Previously we demonstrated that mutations N15A and V25F in the transmembrane domain of SARS-CoV E protein abolished ion conductance in KCl and NaCl solutions (Verdia-Baguaena et al., 2012). New conductance measurements were performed in ERGIC/Golgi membranes in 100 mM CaCl₂ solutions (Fig. 4). Wildtype E protein transmembrane peptide showed conductance values in the range of 110 pS, whereas no conductance was observed for N15A or V25F mutants, indicating that these mutations also inhibited Ca²⁺ transport, and probably prevent all ion passage as it was previously demonstrated that they also failed to transport K⁺, Na⁺ and Cl⁻ (Verdia-Baguaena et al., 2012).

Ca²⁺ transport through SARS-CoV E protein channel activates the NLRP3 inflammasome

Alteration of cellular ion homeostasis by SARS-CoV E protein IC could have several implications. Previously, we linked E protein IC with IL-1β triggered proinflammation in the lungs of mice, leading to epithelial cell damage and death (Nieto-Torres et al., 2014). Higher levels of mature IL-1β were detected in the airways of infected animals when E protein IC activity was present, suggesting that ion conductance could stimulate the inflammasome. To determine whether this was the case, the inflammasome complex was reconstituted in Vero E6 cells by transient transfection of its components (NLRP3, ASC and procaspase-1) and the inactive pro-IL-1β (Lo et al., 2013), in the absence or presence of E protein, with or without IC activity. All the components of the inflammasome, besides the different versions of E protein were efficiently expressed within cells (Fig. 5A). When pro-IL-1β was transfected as a control, no significant level of active IL-1β was detected in the supernatant. However, when all the components were supplied to the cells, the inflammasome was stimulated, and active IL-1β was detected in the media in the range of 600 pg/ml (Fig. 5B). Interestingly, the production of IL-1β was significantly enhanced in the presence of E protein with IC activity (IC⁺) (> 900 pg/ml). This stimulation was IC activity dependent, as the E protein mutants lacking ion conductance (N15A and V25F), represented in the figure as EIC⁻ and EIC⁺ respectively, did not boost IL-1β levels (Fig. 5B). Stimulation levels found with wildtype E protein were in the range of those previously reported for other inflammasome activating proteins, using this system (Lo et al., 2013).

Imbalances in Ca²⁺ within cells have been described as an inflammasome inducer (Ito et al., 2012; Murakami et al., 2012; Triantafillou et al., 2013b). To test the specific contribution of SARS-CoV E protein Ca²⁺ transport to inflammasome activation, the complex was reconstituted in cells in the presence or absence of E protein. Cells were subsequently treated with the cell permeant calcium chelator BAPTA-AM (Fig. 6A). This compound enters cells and binds Ca²⁺ preventing inflammasome activation (Ito et al., 2012). Increasing amounts of BAPTA-AM markedly decreased the levels of secreted IL-1β in the presence of E protein (Fig. 6A, INFL EIC⁺), reaching levels close to those obtained when the inflammasome was assembled alone (Fig. 6A, INFL EIC⁻). The Ca²⁺-ionophore ionomycin stimulated active IL-1β accumulation in the cell supernatant at levels similar to those seen with E protein, further confirming that Ca²⁺ imbalances boost IL-1β production (Fig. 6B). No significant differences in cell viability were found for any of the treatments (Fig. 6C). Collectively, these results indicate that SARS-CoV E protein activates the NLRP3 inflammasome through its Ca²⁺ transport ability.

Discussion

Ion conductive proteins are widely distributed among viruses, being especially common in RNA viruses (Nieva et al., 2012).
Conductance of ions facilitate diverse processes of the viral life cycle such as entry, takeover of organelles to serve as platforms for viral replication, protection of viral proteins from acidic cell compartments, and trafficking of nascent virions (Nieva et al., 2012). In addition, viroporins are often linked to pathogenesis, and in general, mutant viruses lacking them are attenuated, in many cases serving as effective

Fig. 5. Inflammasome activation through SARS-CoV E protein ion channel activity. The components of the NLRP3 inflammasome (INFL), NLRP3 (NLRP3-HA), ASC (ASC-mCherry), procaspase-1 (pro-caspase-1-Myc) and pro-IL-1β were transfected in Vero E6 cells, in the absence or presence of SARS-CoV E protein with (IC1) or without (IC2) ion channel activity. EIC1 represents the N15A mutant and EIC2 indicates the V25F mutant. As a negative control, cells were transfected solely with pro-IL-1β (C−). (A) Levels of active IL-1β present in the cell supernatant. Error bars represent standard deviations from three independent experiments. Statistically significant data are indicated with two asterisks (Student’s t-test p value < 0.01).

Fig. 6. Inflammasome activation through SARS-CoV E protein Ca2+ channel activity. (A) The inflammasome complex (INFL) was reconstituted in cells without or with wildtype E protein (EIC+) in the presence of increasing concentrations (μM) of the cell permeable Ca2+ chelator BAPTA-AM. DMSO was added as negative control (C−). The levels of active IL-1β present in the cell media were measured by ELISA. (B) Activation of the inflammasome by the Ca2+ ionophore ionomycin. Error bars represent standard deviations from three independent experiments; statistically significant data are indicated with two asterisks (Student’s t-test p value < 0.01). Vaccines (DeDiego et al., 2007; Netland et al., 2010; Watanabe et al., 2009; Whitehead et al., 1999). Viroporin removal is frequently accompanied by a defect in viral production, which by itself can explain virulence attenuation. However, recent studies have indicated that IC activity may specifically trigger pathways leading to pathology. Previously we demonstrated that SARS-CoVs proficient in E protein IC activity caused increased damage of the pulmonary epithelia and edema accumulation (Nieto-Torres et al., 2014). These disease symptoms correlated with an immunopathological response mediated by proinflammatory cytokines such as IL-6, TNF and IL-1β, the latter being a crucial mediator of this cascade. IL-1β overproduction is linked to a wide range of inflammatory pathologies including those caused by respiratory viruses (dos Santos et al., 2012; McAuley et al., 2013; Pugin et al., 1996; Triantafillou and Triantafillou, 2014). Here, we report for the first time that CoV E protein formed an IC that transported Ca2+ in ERGIC/Golgi membranes, where this protein localizes, which may have important consequences on cell physiology. In fact, Ca2+ leakage through E protein IC induced the activation of the NLRP3 inflammasome resulting in overproduction of IL-1β. This finding together with previous in vivo observations indicates that IC activity correlates with proinflammation and pathology.

Generally, viroporins form poorly selective ion channels (Nieves et al., 2012). Therefore, the subcellular location where viroporins assemble and the conditions of that particular environment are crucial determinants of their impact on cellular ionic homeostasis. Previously, we reported that SARS-CoV E protein showed mild selectivity for cations (Na+ and K+) when reconstituted in ERGIC/Golgi membranes, mostly conferred by the negative charges of the lipids (Verdia-Baguena et al., 2012, 2013). High concentration gradients are found for Na+ and K+ between the cell interior and the extracellular media (Dubyk, 2004). However, there is no known asymmetric distribution for either of these ion species between the lumen of ERGIC/Golgi and the cell cytoplasm (Chandra et al., 1991; Schapiro and Grinstein, 2000). Accordingly, minimal net transport of Na+ and K+ through E protein pore should be expected, and therefore the biological relevance of these processes may be also limited. In contrast, the ER and Golgi apparatus store high amounts of calcium ions by the action of sarcoendoplasmic reticulum Ca2+ ATPase (SERCA) and the secretory pathway Ca2+ ATPase (SPCA) (Wuytack et al., 2002). This creates an enormous gradient of around 1000-fold between the lumen of these organelles and the cytoplasm (Zhou et al., 2009). The gradient allows controlled eventual and temporal leakages of Ca2+ into the cytoplasm that trigger several processes relevant to cell physiology. Interestingly, we have shown above that SARS-CoV E protein IC was also permeable to Ca2+ in ERGIC/Golgi membranes. Furthermore, Ca2+ interacted with the negative charges of the protein-lipid pore, modulating its properties. Several other viroporins are known to transport Ca2+, resulting in leakage of this cation from its intracellular stores. Rotavirus NSP4 protein as well as Coxsackievirus, encephalomyocarditis virus, and poliovirus 2B proteins deplete ER and/or Golgi Ca2+ concentrations in favor of viral proliferation (Campanella et al., 2004; Crawford et al., 2012; de Jong et al., 2008). Alteration of protein trafficking, manipulation of apoptosis, and control of autophagy are some of the processes controlled by these Ca2+ effluxes. Whether some of these aspects are influenced in a similar manner during SARS-CoV infection will be explored in future experiments.

Protons (H+) are also actively confined to the lumen of the Golgi apparatus and those of the organelles of the secretory pathway in a process that acidifies their interior and creates a gradient with the cytoplasm (Paroultis et al., 2004). Considering that the E protein IC weakly interacts with circulating ions and that pH can modulate its net charge, it is highly likely that protons will also flow through the IC within cells. This is not an isolated case, as several viroporins such as HCV p7 and IAV M2 are known to transport protons, and others such as the 2B protein of the *picornaviridae* family transport both H+ and Ca2+. (de Jong et al., 2006; Wang et al., 1994; Wozniak et al., 2010). Alkalization of the Golgi lumen is crucial to protect acid-sensitive viral progeny and prevent premature activation of viral proteins involved in entry processes (Sakaguchi et al., 1996; Wozniak et al., 2010). SARS-CoV E protein IC mutants did not show profound growth defects, although they were outgrown in competition assays by IC proficient viruses, which suggests better proliferation when E protein ion conductance was present (Nieto-Torres et al., 2014). Whether alkalization of intracellular compartments by E protein IC may assist in SARS-CoV production remains to be explored. Besides these considerations, it cannot be excluded that IC activity may have a greater impact in SARS-CoV production. Inhibition of E protein IC activity may be compensated by the action of two other viroporins encoded by SARS-CoV, the 3a and 8a (Chen et al., 2011; Lu et al., 2006); further experiments are being performed to answer this question.

Disruption of ion homeostasis can have profound deleterious effects for the cells; consequently, they have evolved mechanisms to sense and control these disturbances. Ion imbalances associated with infecting pathogens are recognized by inflammasomes, which are components of the innate immune system. Inflammasomes orchestrate proinflammatory responses to fight viral infections, IL-1β being one of the major players (Strowig et al., 2012). However, increasing evidence indicates that overstimulation of this pathway can lead to undesirable effects for the organism. In fact, immunopathology rather than direct viral destruction of infected cells is the main cause of severe disease in many viral illnesses (McAuley et al., 2013; Meduri et al., 1995; Triantafillou and Triantafillou, 2014). SARS-CoVs that lack E protein IC activity induced less proinflammation and active IL-1β, suggesting that IC activity could be a trigger of this pathway (Nieto-Torres et al., 2014). Indeed, wildtype E protein but not its IC mutants boosted the production of mature IL-1β through the mediation of a reconstituted inflammasome. Ca2+ was the main trigger of this process, as chelation of this ion abolished enhanced IL-1β production, and a Ca2+ ionophore produced a similar simulation. E proteins from other human respiratory CoVs, such as MERS-CoV and HCoV-229E, also display ion channel properties (Surya et al., 2015; Verdia-Baguena et al., 2012; Wilson et al., 2006). Investigating whether these proteins may favor Ca2+ transport and activation of the inflammasome represents a relevant issue. Furthermore, the identification of a possible correlation between the extent of inflammasome activation and the disease symptoms caused by these viruses, highly deleterious in the case of SARS-CoV and MERS-CoV, and mild in the case of HCoV-229E, could provide key information on the impact of this pathway on the pathological outcome induced by different CoVs, and will be analyzed in future experiments.

This study provides new insights into the molecular mechanisms governing CoV viroporin activity and the consequences of this function in viral pathogenesis. What is more, IL-1β overproduction has been related with the pathology induced by SARS-CoV and other respiratory viruses (Triantafillou and Triantafillou, 2014). Our results suggest that development of specific IC inhibitors and implementation of novel compounds decreasing inflammasome driven immunopathology (Coll et al., 2015) may be a valuable complement to other antiviral approaches for the treatment of these infectious diseases.

Materials and methods

Cells

The African green monkey kidney-derived Vero E6 cells were kindly provided by Eric Snijder (Medical Center, University of Leiden, The Netherlands). Cells were grown at 37 °C with an
atmosphere of 98% humidity and 5% CO₂, in Dulbecco’s modified Eagle medium (DMEM, Gibco) supplemented with 25 mM HEPES, 2 mM l-glutamine (SIGMA), 1% non-essential amino acids (SIGMA) and 10% fetal bovine serum (FBS, BioWhittaker).

**Peptide synthesis and ion channel measurements in artificial lipid membranes**

Synthetic peptides representing the full-length SARS-CoV E protein, or its transmembrane domain (amino acids 7–38) containing point mutations that inhibited ion channel activity (N15A and V25F), were generated by standard phase synthesis and containing point mutations that inhibited ion channel activity (N15A and V25F), were generated by standard phase synthesis and purified by HPLC, as previously described (Verdia-Baguena et al., 2012). Ion channels were reconstituted in lipid membranes composed of diphytanoyl phosphatidylcholine (DPhPC), diphytanoyl phosphatidylserine (DPhPS), or a mixture of 59% dioleyl phosphatidylcholine (DOPC), 24% dioleyl phosphatidylethanolamine (DOPE), and 17% dioleyl phosphatidylserine (DOPS) (Avanti polar lipids, Inc., Alabaster, AL). The membranes separated two chambers filled with electrolytic solutions of CaCl₂ or KCl. Ion channel insertion was achieved by adding 0.5–1 μl of a 300 μg/ml solution of synthetic protein or peptides in a acetonitrile/isopropanol (40:60) buffer to one of the chambers (cis). All measurements were performed at room temperature (23 ± 1 °C).

The single-channel conductance was obtained from current measurements under an applied potential of +100 mV in symmetrical salt solutions of 1 M CaCl₂ buffered with 5 mM HEPES at pH 6. The conductance values were evaluated using the Gaussian fit tool of Sigma Plot 10.0 (Systat Software, Inc.). For the selectivity measurements the reversal potential (Erev) was defined as the potential at which non-ion current due to the concentration gradient. Then the ionic current was manually set to zero by adjusting the applied potential. The potential needed to achieve zero current represents the Erev; conversion of Erev into the channel permeability (P₁/P₂) was by done using the Goldman–Hodgkin–Katz (GHK) equation (Hodgkin and Katz, 1949). The effect of Ca²⁺ on E protein ion selectivity was measured in a ten-fold concentration gradient (500 mM / 50 mM). One or several channels were inserted into the bilayer causing a net ionic current due to the concentration gradient. The functional interaction of Ca²⁺ with E protein–lipid pore was evaluated measuring Erev in DPhPC and DPhPS membranes under different pH values, with or without 15 mM CaCl₂.

**Inflammasome reconstitution in Vero E6 cells**

Sub-confluent monolayers of Vero E6 cells seeded onto 24-well plates were transfected using Lipofectamine 2000 (Invitrogen) and a set of plasmids encoding the components of the NLRP3 inflammasome (Lo et al., 2013; Wu et al., 2014): 200 ng of pcDNA4–prol1–1β, 25 ng of pcDNA4–NLRP3–HA, 20 ng pcDNA4–ASC-mCherry, and 10 ng of pcDNA4–pro caspase-1–My c, with 100 ng of empty pcDNA3, as a control, or 100 ng of either pcDNA3–E, pcDNA3–EN15A or pcDNA3–EV25F. Cell lysates and culture supernatants were collected 24 h after transfection. The secreted active IL-1β was measured by ELISA according to the manufacturer’s specifications (eBioscience).

**Cell protein extract preparation and western blot assays**

Cells were lysed in a buffer containing Tris/HCl 10 mM, EDTA 1 mM, NaCl 150 mM, IGEPAL 1%, and complete protease inhibitor (Roche) at pH 8. Inflammasome proteins were detected by western blot using a mouse anti-HA antibody (Sigma) to detect NLRP3–HA, mouse anti-mCherry (Abcam) to bind ASC-mCherry, rabbit anti-Myc (Abcam) to label procaspase-1–Myc, and rabbit anti-human IL-1β (Cell signaling). SARS-CoV E protein was detected using a polyclonal antiserum produced in rabbits (Nieto-Torres et al., 2011). As a loading control, beta-actin was labeled using a mouse monoclonal antibody (Abcam). Bound antibodies were detected using HRP-conjugated goat anti-rabbit IgG and rabbit anti-mouse IgG and the Immobilon Western chemiluminescence substrate (Millipore), following manufacturer’s specifications.

**Effect of BAPTA-AM and ionomycin treatments on inflammasome activation**

Fresh supplemented DMEM containing the indicated concentration of the cell permeant calcium chelator BAPTA-AM (Life technologies) was added to cells 4 h after transfection of the inflammasome components and incubated 30 min at 37 °C. Then, media was removed and a second treatment with fresh media containing BAPTA-AM was performed. Supernatants were collected 20 h post-BAPTA-AM treatment. Ionomycin (Life technologies) was added at 1 μM 4 h after transfection and incubated for 20 h.

**Cell viability assay**

The MTT colorimetric method was used to measure cell metabolic activity. Cell media of transfected cells was replaced by fresh DMEM supplemented with 10% FCS and 500 μg/ml of MTT. Cells were incubated 2 h at 37 °C. After that, media was removed and a solution containing 0.4 M HCl 0.1% Nonidet P-40 in isopropanol was added. Plates were gently mixed to obtain a homogeneous solution, and optic density was measured at 570 nm.

**Acknowledgments**

The work done by the authors was supported by Grants from the Government of Spain (BIO2013-42869-R, FIS2013-40473-P), Generalitat Valenciana (Prometeo 2012/069), Fundació Caixa Castelló-Bancaixa (P1-1B2012-03) and a U.S. National Institutes of Health (NIH) project (5P01 AI060699). JLN, JM and JR received contracts from NIH. CCR received a contract from Fundacion La Caixa. We thank professor Ming-Zong Lai (Institute of Molecular Biology, Taipei) for kindly providing us plasmids encoding the inflammasome components. We thank Marga Gonzalez for her technical assistance.
