ABSTRACT

A novel gain boosted folded cascode Op-Amp using simple single stage auxiliary amplifiers is presented. The proposed auxiliary amplifiers are designed in a way that has proper input and output DC common mode voltage without using common mode feedback network. The inputs of the auxiliary amplifiers are insulated by the coupling capacitors and floating-gate MOS transistors. Thus, the DC input voltage level limit has been removed. Diode connected transistors are also used in the output of the auxiliary amplifiers, which keep the output voltage level at the desired. A simple single stage auxiliary amplifier imposes fewer poles and zeroes on the main amplifier compared to more complicated amplifiers where consumes also less power consumption. Simulation results in a 0.18μm CMOS technology show a DC gain enhancement of about 20 dB while output swing, slew rate, settling time, phase margin, and gain-bandwidth retain almost as the same as previous folded cascode design.

1. INTRODUCTION

One of the most popular approaches in designing high speed operational transconductance amplifiers (OTA) is the folded cascode (FC) architecture. Its popularity comes from high unity gain frequency, good output, and input swing. However, it has limitations to provide high DC gain which is required for some mixed-mode circuits like data converters. Active gain boosted folded cascode (GBFC) is presented first by Hosticka [1]. Through this technique, the output resistance and total gain can be increased by the gain of an auxiliary amplifier. This method increases the voltage gain without degrading its high-frequency performance. However, the GBFC introduces a pole-zero pair (doublet), which potentially leads to slow-settling behaviour of such op-amps [2,3,4].

The well-known active gain-boosting technique consists of the main amplifier and two auxiliary amplifiers is shown in Figure 1 [5]. By removing the auxiliary amplifiers and connecting the gate transistors of M5,6 and M7,8 to the appropriate bias voltages; a traditional folded cascode amplifier is shown in Figure 1. The auxiliary amplifiers should be operated at the specific input and output common mode voltages and therefore they usually utilize two individual common mode feedback networks [6].

There are also other methods presented in literatures that focus mostly on increasing the slew rate while their gain enhancement is not impressive [7-11]. Also, many applications like switched capacitor circuits demand a high gain one stage Op-Amp [12,13].

In this paper, a simple differential amplifier with positive feedback load has been utilized as an auxiliary amplifier. For this reason, the auxiliary amplifiers do not need their own common mode feedback circuit. As described later, coupling capacitors are used at the input of the auxiliary amplifiers so that there is no limit to the DC voltage range of the auxiliary amplifier input. Also, two different types of the auxiliary amplifiers with two different DC output voltage levels have been utilized for the purpose of providing proper output bias voltage.

2. PROPOSED AMPLIFIER

Figure 2 illustrates the equivalent half-circuit of the GBFC shown in previous figure. The body effect is ignored.
Using KVL and KCL, the DC gain of the circuit can be written as:

$$\frac{v_{od}}{v_{in}} = -g_{m1}\frac{A_k\beta g_m r_o (r_{o1}) - 2A_k\beta g_m r_o (r_{o2}) - A_k (r_{o1} + r_{o2}) + g_m r_o (r_{o1} + r_{o2}) + 2 (r_{o1} r_{o2})}{r_m 5\beta 5 + r_o 5 (r_{o1} + r_{o2})}$$

where the voltage gain of both auxiliary amplifiers, $A_x$, is almost assumed the same and relatively large. Also, $r_{o5} = r_{o6}$ is considered. As can be seen, the voltage gain of the GBFC is approximately $A_x$ times of FC.

The input DC voltage level of the first auxiliary amplifier $A_1$ ($V_{X1}$ and $V_{X2}$) is about one overdrive voltage of $M_{1A}$ and $M_{2A}$ (V_D+5) and the output common mode voltage of $A_1$ should be around at $V_{GS5b}$ for the output swing considerations. The proposed circuit of $A_1$ is illustrated in Figure 3a. As shown in this figure, gates of $M_{1B}$ & $M_{2B}$ isolated by coupling capacitors $C_{1a}$ and $C_{2a}$ from the main amplifiers, and the gate DC voltage level of $M_{1B}$-$M_{2B}$ is supplied through quasi-floating gate transistors $M_{2a}$ & $M_{3a}$ which act as large resistors to $V_{D}$ [14].

The output common mode voltage of $A_1$ is stabilised by diode connected transistors $M_{5a}$ & $M_{6a}$ without using individual common mode feedback network at the DC voltage $V_{GS5b}$ which is proper for a driving gate of $M_5$ and $M_6$ transistors. The DC gain of $A_1$ can be obtained by:

$$A_X = g_{m1a} R_X$$

$$R_X = \left(g_{m1a}^2 + g_{ds1a} + g_{ds2a} + g_{ds3a} + g_{ds4a}\right)^{-1}$$

while the value of $g_{m1a}$ and $g_{m2a}$ is approximately selected to 90 and 80 percent of $g_{m3a}$ and $g_{m5a}$, respectively, to control the probable destructive effect of positive feedback [15]. In the same way, auxiliary amplifier $A_2$ has the same DC gain as $A_1$ and input coupling capacitors $C_{1b}$ & $C_{2b}$ as shown in Figure 3b. The output common mode voltage of $A_2$ is adjusted by diode connected $M_{1B}$ & $M_{2B}$ at dc level of $V_{D}$-$V_{GS5a}$ which is proper for biasing the gates of $M_5$ & $M_6$.

Boosting technique added a pole-zero doublet into the transfer function of GBFC. It can be shown that the zero location $\omega_Z$ is approximately equal to $(1 + A_X)\omega_X$ where $\omega_X$ is the 3 dB cut-off frequency of auxiliary amplifiers and the zero is right close to its doublet pole [5, p.372]. The zero location $\omega_Z$ can be written as:

$$\omega_Z \approx A_X \omega_X \approx g_{m1a} R_X \frac{1}{R_X C_X} \approx \frac{g_{m1a}}{C_X}$$

where $C_X$ donates the total load capacitance in the output of the auxiliary amplifier [16].

Hence, increasing the bias current of $A_1$ & $A_2$ has resulted in to greater $g_{m1a}$; therefore, higher value of zero location of $\omega_Z$. The larger ratio of $\omega_Z$ to the unity frequency $\omega_0$, the smaller the doublet effect [3]. Hence, with adjusting the tail current sources of $A_1$ & $A_2$ (Id9a & Id9b) slow settling caused by the doublet effect can be suppressed. The second pole location of the proposed auxiliary amplifier is far from its unity gain frequency and can be ignored. However, most of the reported GBFC amplifiers utilizing extra FC with a considerable
secondary pole as an auxiliary amplifier which imposes a new pole to the main amplifier transfer function. Table 1 summarized the transistor sizes of the presented GBFC amplifier.

It should be noted that the amount of the $C_{1a}, C_{2a}, C_{1b},$ and $C_{2b}$ should be large enough to ignore the parasitic capacitors located in the gate of transistors $M_{1a-2a}$ and $M_{1b-2b}$. For example, in Figure 3a, the effect of the parasitic capacitors located at the gates of $M_{1a}$ and $M_{2a}$ in differential mode small signal analysis can be written as:

$$v_{g1a} = \xi v_{X1}; \quad \xi = \frac{C_{1a}}{C_{1a} + C_{Par}}, \quad C_{Par} \cong C_{GSS1a}. \quad (5)$$

In this paper, the value of $C_{1a}$ is considered to 0.5 pF which be much larger than the $C_{Par}$, so the $\xi$ value is very close to one (about 0.98).

3. SIMULATION RESULTS

The two amplifiers were simulated in $0.18\mu$m BSIM3v3 level 49 CMOS technology with 1.8 V of supply voltage by Hspice. The value of load capacitors $C_{1L} & C_{2L}$ is 5 pF for both of the amplifiers. The frequency response of the amplifiers is shown in Figure 4 which shows DC gain enhancement of about 20 dB. A simple inverting amplifier with unity gain shown in Figure 5 is proposed for transient time simulation where $C_{1} = 1.5\text{ pF}$ and $R_{1} = ...

Table 2. Simulation results summary

| Parameter                | FC   | GBFC |
|--------------------------|------|------|
| Power Supply             | 1.8  | 1.8  |
| Power Dissipation        | 873  | 1018 |
| DC Gain(dB)              | 42.2 | 61.9 |
| 1% Settling Time (nS)    | 76.8 | 83.4 |
| Unity Gain Frequency(MHz)| 58.5 | 54.1 |
| Phase Margin(deg)        | 88.5 | 88.1 |
| Diff. Output Swing(V)    | 2.4  | 2.4  |

5 MΩ. A square wave voltage with a range of ±1.2 V and a frequency of 2 MHz is applied to its differential input. The simulated differential outputs of the two circuits are shown in Figure 6. The simulation results summary is given in Table 2.

As can be seen, despite the increase in a voltage gain of the proposed amplifier, the maximum output swing of both amplifiers is the same. This is because the addition of auxiliary amplifiers has not caused any change in the DC operating point of the main transistors (M0-M15) in Figure 1.

To evaluate the effect of auxiliary amplifiers and validity of Equation (1), the frequency response of the auxiliary amplifiers is shown in Figure 7. As can be seen voltage gain of these amplifiers is about 22 dB which close to the enhancement gain of the GBFC over the FC.

Also, Table 3 presents the frequency characteristics of the proposed Op-Amp at different process corners. As can be seen, the GBFC has at least about 61.2 dB gain and 88.1° of phase margin at different process corners. Also, the value of the phase margin is considered under a capacitive load of 1 pF and 10 pF which resulted in 76.7° and 88.9°, respectively.

The locations of the poles and zeros of the two amplifiers are shown in Table 4. It can be seen that the pole-zero doublets (-175 & -246 MHz) are large enough in comparison to the unity-gain frequency (ωU) of the GBFC where ωU is around 54 MHz. As illustrated by Ju and Lee [17], if the pole-zero doublet natural frequency is approximately four times the ωU, their destructive effect on the step response can be ignored, which is almost the case here as well. It should be noted that the low-frequency pole and zeros below 1 Hz are omitted in Table 4.

Table 3. Proposed GBFC performance at different process corners with C_L=2×5pF

| Process Corner | TT   | SS   | SF   | FS   | FF  |
|----------------|------|------|------|------|-----|
| DC Gain(dB)    | 61.9 | 61.2 | 61.8 | 61.8 | 62.3|
| Unity Gain Frequency (MHz) | 54.1 | 52   | 55.3 | 51.9 | 58.3|
| Phase Margin(deg) | 88.1 | 88.1 | 88.2 | 88.3 | 88.3|
| Average 1% Sett. Time (nS) | 83.4 | 118.5| 108.3| 98.2 | 81.9|
TABLE 4. The location of poles and zeroes

|        | Poles (MHz) | Zeroes (MHz) |
|--------|-------------|--------------|
| FC     | -0.355      | -6771        |
|        | -2280       |              |
| GBFC   | -175.8324   | -175.8270    |
|        | -246.7793   | -246.6072    |
|        | -634.5±423.6i | -620.09     |
|        | -0.0402     |              |

Note that both of the amplifiers have almost the same slew rate, unity gain frequency, phase margin, output swing range, and settling time while the proposed amplifier shows DC gain enhancement of about 20 dB. The power consumption of the GBFC is 1.02 mW while the FC amplifier consumes 0.87 mW, meaning the additional auxiliary amplifiers only consumed 0.145 mW or 14 percent of total power consumption.

4. CONCLUSION

Using two simple single stage amplifiers, the GBFC is presented. To achieve a proper swing at the output of the main amplifier, the input and output DC voltage levels of the auxiliary amplifiers must be set to certain values. The inputs of the auxiliary amplifiers are insulated by the coupling capacitors and therefore they can operate at any input DC voltage level. Diode connected transistors are also used in the output of the auxiliary amplifiers, which keep the output voltage level at the desired level without using an additional common mode feedback circuit. Simulation results show a DC gain enhancement of about 20 dB without degrading the output swing and phase margin. The slow settling behaviour arising from the pole-zero doublet is also suppressed since the zero from the single stage auxiliary amplifier is shifted far from unity gain frequency.
