ABSTRACT

Context. Numerous complex organic molecules have been detected in the universe among which amides are considered as models for species containing the peptide linkage. Acrylamide (CH\textsubscript{2}CHC(O)NH\textsubscript{2}) bears in its backbone not only the peptide bond, but also the vinyl functional group which is a common motif in many interstellar compounds. This makes acrylamide an interesting candidate for a search in the interstellar medium. In addition, a tentative detection of the related molecule propionamide (C\textsubscript{3}H\textsubscript{5}C(O)NH\textsubscript{2}) has been recently claimed toward Sgr B2(N).

Aims. The aim of this work is to extend the knowledge of the laboratory rotational spectrum of acrylamide to higher frequencies, which makes possible to conduct a rigorous search for interstellar signatures of this amide by millimeter wave astronomy.

Methods. The rotational spectrum of acrylamide was investigated between 75 and 480 GHz. After its detailed analysis, we searched for emission of acrylamide in the imaging spectral line survey ReMoCA performed with the Atacama Large Millimeter/submillimeter Array toward Sgr B2(N). We also searched for propionamide in the same source. The astronomical spectra were analyzed under the assumption of local thermodynamic equilibrium.

Results. We report accurate laboratory measurements and analyses of thousands rotational transitions in the ground state and two excited vibrational states of the most stable syn form of acrylamide. In addition, we report an extensive set of rotational transitions for the less stable skew conformer. Tunneling through a low energy barrier between two symmetrically equivalent configurations has been revealed for this higher-energy species. Neither acrylamide nor propionamide were detected toward the two main hot molecular cores of Sgr B2(N). We did not detect propionamide either toward a position located to the east of the main hot core, thereby not confirming the recent claim of its interstellar detection toward this position. We find that acrylamide and propionamide are at least 26 and 14 times, respectively, less abundant than acetamide toward the main hot core Sgr B2(N1S), and at least 6 and 3 times, respectively, less abundant than acetamide toward the secondary hot core Sgr B2(N2).

Conclusions. A comparison with results of astrochemical kinetics model for related species suggests that acrylamide may be a few hundred times less abundant than acetamide, corresponding to a value at least an order of magnitude lower than the observational upper limits. Propionamide may be as little as only a factor of two less abundant than the upper limit derived toward Sgr B2(N1S). Last but not least, the spectroscopic data presented in this work will aid future searches of acrylamide in space.

1. Introduction

The peptide bond, –C(=O)NH–, found in amides is vital for biology. It provides linkages between amino acids, giving rise to peptides, which are the key players in mediating both the molecular interactions underpinning present life on Earth and potentially the prebiotic processes that preceded it (Frenkel-Pinter et al. 2020; Weber & Pizzarello 2006). Therefore, it is not surprising that the question of peptide bond formation represents a highly topical theme in different fields and disciplines, including prebiotic astrochemistry (Ruiz-Mirazo et al. 2014; Sandford et al. 2020; Stolar et al. 2021).

In astronomical settings, amides and other peptide-like species are actively searched for in star-forming regions, protostars and other environments (e.g. Halfen et al. 2011; Belloche et al. 2017; Mendoza et al. 2018; Ligterink et al. 2020; Gorai et al. 2020; Colzi et al. 2021). These studies uncover their formation in space and their role as nodes in chemical networks connecting other prebiotic molecules. Remarkable progress has been made in increasing the sensitivity of astronomical observing capabilities (Jørgensen et al. 2020; Tercero et al. 2021), opening up unique possibilities to observe new target compounds in lower abundances than before. Much experimental work has concentrated on laboratory simulations de-
signed to mimic the interstellar ices and provided compelling evidence that molecules containing the peptide bond can be formed abiotically (see, e.g., Kaiser et al. 2013; Ligterink et al. 2018; Frigge et al. 2018). Finally, possible formation and destruction pathways of peptide-like molecules became an important target in theoretical calculations and chemical modeling (see, e.g., Redondo et al. 2013, 2014; Rimola et al. 2018; Barone et al. 2015; Quénard et al. 2018). All these studies provide valuable information on the peptide bond chemistry in space from different viewpoints, but sharing the same goal: to contribute to the deciphering of one of the most enduring puzzles presented to humankind: the origins of life.

Laboratory rotational spectroscopy is one of the key pillars in decoding the prebiotic inventory of space. It has contributed to the detection of several amides among other prebiotically interesting molecules (McCauley 2018) of which glycolaldehyde (CH₂OHCHO; Hollis et al. 2000), aminoacetonitrile (NH₂CH₂CN; Belloche et al. 2008), hydroxylamine (NH₂OH; Rivilla et al. 2020), and ethanalamine (NH₂CH₂CH₂OH; Rivilla et al. 2021) are mentioned as examples. The simplest member of the amide family, formamide (NH₂CHO), has been observed in spectral-line rich sources, namely Sgr B2 (Rubin et al. 1971; Gottlieb et al. 1973; Nummelin et al. 1998; Turner 1989; Thiel et al. 2017; Orion KL Turner 1989; Motylenko et al. 2012), IRAS 16293–2422 (Kahane et al. 2013; Coutsou et al. 2016) and, more recently, in many other sources (see, e.g., López-Sepulcre et al. 2019). Also recently, N-methylformamide (CH₃NHCHO) has been discovered toward the Sgr B2 and NGC 6334I star-forming regions (Belloche et al. 2017; 2019; Ligterink et al. 2020) in which its structural isomer acetamide (CH₃C(O)NH₂) had also been detected (Hollis et al. 2006; Halfen et al. 2011; Belloche et al. 2013; Ligterink et al. 2020). Very recently, a tentative detection of propionamide (CH₃CH₂C(O)NH₂) toward Sgr B2 has been claimed by Li et al. (2021). These detections suggest that more peptide bond bearing molecules are yet to be detected.

Another species with the peptide link is acrylamide (CH₂CH(C(O)NH)₂). It contains two hydrogen atoms fewer than propionamide and shares the vinyl functional group with other known interstellar compounds such as vinyl cyanide (CH₂C≡CN; Gardiner & Windt 1973), vinyl alcohol (CH₂CHOH; Turner & Apponi 2001), propenal (CH₂C(=O)H; Hollis et al. 2004), propylene (CH₂CH₂C=CH; Marcelino et al. 2007), vinylacetylene (CH₂CHC≡CH; Cerrieharo et al. 2021), and vinylcyanoacetylene (CH₂C≡C(NH)H; Lee et al. 2021).

Acrylamide is a complex organic molecule (COM) in the astronomical sense (i.e., containing six atoms or more: Herbst & van Dishoeck 2009). Since COMs might be present in multiple conformations which, in addition, might be governed with large amplitude motions and low-frequency vibrations, their dense rotational spectra might be difficult to interpret. Extensive spectroscopic studies of complex amides such as N-methylformamide (Belloche et al. 2017), glycolaldehyde (Sanz-Novo et al. 2020), propionamide (Alonso et al. 2021), and glycynamide (Kisiel et al. 2021) were thus conducted to enable their interstellar hunt in the millimeter wave region. However, so far this has not been the case for acrylamide for which the rotational spectrum has been studied only up to 60 GHz (Marstokk et al. 2000). This makes predictions at higher frequencies rather uncertain impeding its rigorous search in space.

As an isolated molecule in the gas phase, acrylamide exists in the form of syn and skew conformers (see Fig. 1), of which the latter was found by Marstokk et al. (2000) to be 6.5(6) kJ mol⁻¹ or 543(50) cm⁻¹ less stable. In course of the present work, we measured the rotational spectrum of acrylamide between 75 and 480 GHz and analyzed the spectral signatures of both species. The new measurements and analyses presented here provided precise laboratory information to search for this amide in the high-mass star-forming region Sgr B2(N), a possible source of large peptide molecules.

The remainder of the paper is structured as follows. Details about the laboratory spectroscopy are given in Sections 2 and 3 while the search for acrylamide toward Sgr B2(N) is reported in Sect. 4. In the same Section, we also report our search for propionamide in Sgr B2(N) which does not confirm its recently claimed interstellar detection. We discuss our results in Sect. 5 and provide our conclusions in Sect. 6.

2. Experiments

White crystalline acrylamide (m.p. 82–86 °C) was obtained commercially and was used without any further purification. The room-temperature rotational spectrum was measured in the frequency region 75–480 GHz using two spectrometers. The lowest-frequency (75–110 GHz) and the highest-frequency (100–480 GHz) sections were recorded using the millimeter wave spectrometer at the University of Valladolid (Dalv et al. 2014) which is based on sequential multiplication of an Agilent synthesizer produced frequency by a set of active and passive multipliers from Virginia Diodes, Inc. The absorption free-space cell was a glass tube (10 cm diameter, 360 cm long). The Prague millimeter wave spectrometer (Kania et al. 2008) which is based on the same principle was used to measure the rotational spectrum between 128 and 170 GHz. Here, the free-space cell was 280 cm long with a diameter of 8 cm. The optical path length was doubled by a roof-top mirror in both cases. The synthesizer output was frequency modulated in both spectrometers (modulation frequency of 10.2 and 28 kHz) and the detection system was completed by a demodulation procedure achieved by a lock-in amplifier that was tuned to twice the modulation frequency. All spectra were registered with the sample pressure between 10 and 20 μbar by upward and downward frequency scanning and averaged. The individual spectral sections were merged into a single spectrum and subjected to the analysis using the Assignment and Analysis of Broadband Spectra (AABS) package (Kisiel et al. 2005, 2012).

Fig. 1. The two conformers of acrylamide depicted in their principal ab and ac inertial planes.
3. Rotational spectra and analyses

3.1. Syn conformer

The only available previous microwave study had shown that the syn conformer of acrylamide is essentially planar with a large dipole moment component along the b principal inertial axis \(|\mu_b| = 0.269(3)\) D, \(|\mu_a| = 3.42(2)\) D, \(|\mu_c| = 0.12(24)\) D; Marstokk et al. 2000. At the initial stage of the analysis, predictions based on the spectroscopic constants from Marstokk et al. 2000 were used. Strong lines corresponding to pairs of b-type R-branch transitions \((J+1)_0, J+1 \leftrightarrow J_0, J\) and \((J+1)_0, J+1 \leftrightarrow J_1, J\) were readily assigned as they are visibly getting closer to each other with increasing \(J\) quantum number. They finally coalesce into very prominent, doubly degenerate lines that stand out in the millimeter wave region in Fig. 2a. On the other hand, groups of b-type R-branch transitions are gradually formed on the way to the sub-millimeter wave region (see Fig. 2b). Many b-type Q-branch transitions could also be identified throughout the spectrum. Finally, a-type transitions were searched for but could not be observed. Graphical Loomis–Wood-type plots produced with the AABS package (Kistel et al. 2005, 2012) greatly facilitated the line assignments. Some of the observed lines were found partially split due to the nuclear quadrupole coupling interactions of a single \(^{14}\)N nucleus. They were not further taken into consideration due to the distorted line shapes.

We measured more than 2500 lines which encompass the rotational transitions with \(J\) and \(K_a\) quantum numbers up to 78 and 33, respectively. These transitions were ultimately merged with a selection of transitions from Marstokk et al. 2000 which were available in the microwave catalog from Ulm. Like our data set, this selection contained the rotational transitions for which the nuclear quadrupole hyperfine structure was expected to be collapsed. The fits and predictions were made in terms of Watson’s \(A\)-reduced Hamiltonian in \(F\)-representation (Watson 1977). The broad coverage of transition types and quantum numbers ensured the precise determination of the rotational constants and full sets of the quartic and sextic centrifugal distortion constants. Their values are collected in Table 1 while the list of measured transitions is provided in Table A.1.

Several excited vibrational states were observed for the syn conformer by Marstokk et al. 2000. The low-frequency C–C torsional mode in this conformer, which under the \(C_s\) point group is labeled \(v_{24} (A'')\), was found to be a dominating contributor to the vibrational satellite pattern which was also observed in our records (see Fig. 3). Its frequency was estimated...

Notes. (a) The numbers in parentheses are the parameter uncertainties in units of the last decimal digit. Their values are close to 1σ standard uncertainties (67% confidence level) because the unitless (weighted) deviation of the fit is close to 1.0. SPFIT/SPCAT program package [Pickett 1991] was used for the analysis. (b) Fixed to the ground state value which is usually a preferred constraint against the zero or poorly determined value [Urban & Salka 1990, Kowey et al. 2013]. (c) Number of distinct frequency lines in the fit. (d) Root mean square deviation of the fit. (e) Unitless (weighted) deviation of the fit.

Fig. 3. Vibrational satellite pattern of the syn conformer in the millimeter wave spectrum of acrylamide. The upper panel shows a pair of degenerate $4v_1 = 1, 4v_1 = 2$ {$4v_1 = 1, 4v_1 = 2$} transitions for the ground state (G.S) and the excited vibrational states (yellow diamonds). The green circle symbols represent the ground state lines included in the fit. The lower panel illustrates a stick reproduction of the ground state and $v_2 = 1, 2$ spectra using the spectroscopic constants from Table 1.

Fig. 3. Vibrational satellite pattern of the syn conformer in the millimeter wave spectrum of acrylamide. To 90(10) cm$^{-1}$ from the microwave relative intensity measurements [Marstokk et al. 2000]. We were able to build upon results from Marstokk et al. (2000) and follow the successive excitation of this mode up to $v_2 = 4$. However, only $v_3 = 1$ and $v_3 = 2$ could be analyzed using the same Hamiltonian as for the ground state and their spectroscopic constants are given in Table 1. The rotational transitions in $v_3 = 3$ and $v_3 = 4$ suffered from perturbations. These perturbations are not surprising since the manifold of vibrational energy levels becomes denser above 200 cm$^{-1}$. In the neighborhood of $v_3 = 3$, which under the harmonic approximation can be estimated at 270 cm$^{-1}$, there are first excited states of two other normal vibrational modes: $v_23$ (A’’) and $v_17$ (A’) which are associated with NH2 wagging and C=C-C in-plane bending motions, respectively. Their fundamentals were observed at 262.8 cm$^{-1}$ and 307 cm$^{-1}$ using infrared and Raman spectroscopies on gas phase (Kydd & Dunham 1980) and solid phase samples (Duarte et al. 2005), respectively. Microwave relative intensity measurements provided values of 235(40) cm$^{-1}$ and 307(40) cm$^{-1}$ for $v_3 = 1$ and $v_17 = 1$, respectively [Marstokk et al. 2000]. Due to the proximity of vibrational energy levels, significant vibration-rotation interactions might be thus manifested in pure rotational spectra of these states. This proximity is apparent from Fig. 3, where the same rotational transitions in $v_3 = 3$, $v_2 = 1$, and $v_17 = 1$ reveal very similar relative intensities. Practically the same situation seems to occur also for $v_3 = 4$ which is energetically accompanied by combination states ($v_3 = 1$, $v_3 = 2$ and $v_3 = 1, v_1 = 1$).

We note that we were able to identify the rotational transitions in all these excited vibrational states in our records (see Fig. 3), in agreement with the assignments from Marstokk et al. (2000). Many lines for these states could be confidently assigned using the Loomis–Wood-type plots but could not be treated in the scope of the semi-rigid rotor Hamiltonian due to clear ev-
a sizable dipole moment component only along the D,  suggests a rather complex and time-consuming treatment, probably requiring two three-state Hamiltonian fits. We are planning to search for rotational transitions of the less stable skew conformer of $E_{skew} = 543$ cm$^{-1}$ taken from Marstokk et al. (2000).

idences of perturbations. An inspection of these perturbations suggests a rather complex and time-consuming treatment, probably requiring two three-state Hamiltonian fits. We are planning to search for rotational transitions of the less stable skew conformer of $E_{skew} = 543$ cm$^{-1}$ taken from Marstokk et al. (2000).

Finally, we provide in Table 2 partition functions of syn acrylamide needed to estimate the column density. The rotational partition function ($Q_{rot}$) was evaluated by summation of the Boltzmann factors over the energy levels in the ground vibrational state. We used the SPCAT program (Pickett 1991) to undertake this summation numerically employing the spectroscopic constants from Table 1 and all rotational states up to $J = 120$. The vibrational partition function ($Q_{vb}$) was obtained using the Eq. 3.60 of Gordy & Cook (1970) by taking into account the frequencies of twenty-four normal vibrational modes from Table A.2 of the Appendix.

3.2. Skew conformer

Spectroscopic constants from Marstokk et al. (2000) were used to search for rotational transitions of the less stable skew conformer in our records. Since the candidate lines were significantly weaker and were displaced by a few MHz from the predicted positions, a double check for the correct assignment in the very dense spectrum was the simultaneous observation of $a$ and $b$-type transitions. Unlike the syn form, which possesses a sizable dipole moment component only along the b principal axis, the skew conformer is endowed with large dipole moment components along the a and b axes ($|\mu_a| = 2.81$ D, $|\mu_b| = 3.02$ D, $|\mu_c| = 1.00$ D as calculated by Marstokk et al. (2000) at the MP2=full/cc-pVTZ level of theory). For certain values of J this leads to the observations of easily discernible quartets in which the two b-type transitions straddle the pair of a-type transitions. This is clearly illustrated in Fig 2 which shows a small part of the spectrum at 154 GHz.

In this study, we assigned transitions belonging to the ground state and a higher-frequency satellite matching with what was assumed to be the first excited C–C torsional state in Marstokk et al. (2000). Relative intensity measurements undertaken by Marstokk et al. (2000) placed this state into the energy window between 71 and 111 cm$^{-1}$ above the ground state. On the other hand, our records indicate that this state lies significantly lower; its rotational lines apparently presented intensities very similar to those of the corresponding lines in the ground state. An examination of the Loomis–Wood-type plots made it further possible to identify several level crossing perturbations. They were observable in mirror-image form for the ground state and the satellite lines, presenting evidence that these two states are in close proximity and are in mutual interaction.

An explanation for the observation of such an interacting pair of states could be a double-minimum potential for skew acrylamide which we subsequently confirmed by means of a potential energy surface scan for the rotation about the central C–C bond. As shown in Fig. 4 two minima corresponding to two symmetrically equivalent non-planar skew structures are separated by a small barrier. In this scenario, the ground vibrational state, normally labeled $v = 0$, is expected to be observed in the form of a doublet, the members of which are designated $0^+$ and $0^-$. These two states are often affected by vibration-rotation interactions as shown, for example, for glycinamide (Kisiel et al. 2012), cyanamide (Kisiel et al. 2013), 2-hydroxyacetanilide (Marqueles et al. 2012), and $dG^{2p}$ ethylene glycol (Christen & Müller 2003). The identification of characteristic mirror-image perturbation spikes for various $K_v$, i.e. frequency shifts with respect to the unperturbed positions (see, e.g., Kisiel et al. 2013), allowed us to unambiguously assign the higher-frequency satellite to the higher-energy $0^-$ state. Furthermore, their precise location in J and $K_v$ allowed rather confident estimation of the energy difference $\Delta E = E^{0^-} - E^{0^+}$ $\approx 13.8$ cm$^{-1}$. This value was used as an estimate in the fitting procedure that employed a two-state Hamiltonian in the following matrix form

\[ H_{eff} = \begin{pmatrix} H_{rot}^{0^+} & H_{cor}^{0^+,0^-} \\ H_{cor}^{0^+,0^-} & H_{rot}^{0^-} + \Delta E \end{pmatrix} = \begin{pmatrix} H_{rot}^{0^+} & H_{rot}^{0^+,0^-} \\ H_{rot}^{0^+,0^-} & H_{rot}^{0^-} \end{pmatrix} + \Delta E \]

where $H_{rot}^{0^+}$ and $H_{rot}^{0^-}$ represent Watson’s A-reduced semi-rigid rotor Hamiltonians in $I^\prime$-representations (Watson 1977) for $0^+$ and $0^-$ states, respectively. The off-diagonal coupling term $H_{cor}^{0^+,0^-}$ is based on a reduced axis system (RAS) approach of

![Fig. 4. Potential energy surface scan for the skeletal torsion calculated at the B3LYP/cc-pVTZ level of theory using the scan option of Gaussian 16 (Frisch et al. 2016). The energies were calculated in steps of 10° of the dihedral angle O2–C1–C6–C7 while the other structural parameters were optimized under the verytight convergence criterion. The global minimum belongs to the planar syn conformer while for the higher-energy conformer two minima can be identified on the surface which correspond to two equivalent skew frameworks connected with a barrier of around 1 kJ mol$^{-1}$ (84 cm$^{-1}$).](image-url)

Notes. (a) The ground state and the excited C–C torsional state in [Marstokk et al. (2000)] correspond to \(0^+\) and \(0^-\) states, respectively. (b) The numbers in parentheses are the parameter uncertainties in units of the last decimal digit. Their values are close to \(1\sigma\) standard uncertainties (67% confidence level) because the unitless (weighted) deviation of the fit is close to 1.0. SPFIT/SPCAT program package [Pickett (1993)] was used for the analysis. (c) Number of distinct frequency lines in the fit. (d) Root mean square deviation of the fit. (e) Unitless (weighted) deviation of the fit.

Final remarks concern the quartic and sextic centrifugal distortion constants in Table 3. Their values in \(0^+\) and \(0^-\) tunneling states are generally close to each other, however, a difference might be perceivable, for example, for \(\Delta_3\). The main difficulty here was the high spectral density caused by the existence of the more stable \(syn\) conformer and its rotational lines in many excited vibrational states. It was sometimes rather difficult to evaluate whether the lines are obscured by these features or are still perturbed or simply are not observed due to their weakness and our limited signal to noise ratio. It is therefore possible that the perturbation contributions are treated incompletely. Nevertheless, the measured data set for skew acrylamide is relatively large and is reproduced near the experimental uncertainty using the spectroscopic parameters from Table 3.

4. Search for acrylamide and related molecules toward Sgr B2(N)

4.1. Observations

We used the imaging spectral line survey ReMoCA (Reexploring Molecular Complexity with ALMA) performed with the Atacama Large Millimeter/submillimeter Array (ALMA) to search for acrylamide toward Sgr B2(N). The observational strategy and the method employed to reduce the data of this survey were—

(k) The upper limit was derived from the REoMA survey by Alonso et al. (2021).

We did not take into account the contribution of local thermodynamic equilibrium (LTE), which is appropriate given the high densities that characterize Sgr B2(N)’s hot cores ($> 1 \times 10^{5}$ cm$^{-3}$, see Bonfand et al. 2019). A best-fit synthetic spectrum of each molecule was derived separately, and then the contributions of all identified molecules were added together. Each species was modeled with a set of five parameters: size of the emitting region ($\theta_i$), column density ($N$), temperature ($T_{\text{rot}}$), linewidth ($\Delta V$), and velocity offset ($V_{\text{vol}}$) with respect to the assumed systemic velocity of the source, $V_{\text{sys}} = 50$ km s$^{-1}$ for Sgr B2(N1S) and $V_{\text{sys}} = 74$ km s$^{-1}$ for Sgr B2(N2).

4.2. Nondetection of acrylamide

To guide our search for the syn conformer of acrylamide in the ReMoCA spectra of Sgr B2(N1S) and Sgr B2(N2), we computed LTE synthetic spectra of this molecule on the basis of the parameters derived for acetamide, CH$_2$C(O)NH$_2$, by Belloche et al. (2019) and Belloche et al. (2017), respectively. Only the column density of acrylamide was kept as a free parameter. We searched for rotational lines in its vibrational ground state, $v = 0$, and in its vibrationally excited states $v_2 = 1$ and $v_2 = 2$. No evidence for emission of acrylamide was found toward either source. The nondetection toward Sgr B2(N1S) and Sgr B2(N2) is illustrated in Figs. 8 and 9 of Belloche et al. (2017), respectively, and the upper limits to the column density of acrylamide are indicated in Tables 2 and Table 5, respectively. The tables also recall the parameters that we previously obtained for acetamide and propionamide. We did not take into account the contribution of the skew conformer of acrylamide to its partition function. This conformer is observed as a tunneling doublet about 540 cm$^{-1}$ above the...
Table 6. Column density upper limit derived for propionamide toward the offset position (1.58",−2.72") with respect to the phase center.

| Molecule                  | Status | No. | \( \theta_\text{syn} \) | \( T_\text{rot} \) (K) | \( N^\alpha \) \( \text{cm}^{-2} \) | \( F_{\text{vib}} \) | \( \Delta V^\alpha \) (km s\(^{-1}\)) | \( V_{\text{obs}} \) (km s\(^{-1}\)) |
|---------------------------|--------|-----|----------------|----------------|----------------|----------------|----------------|----------------|
| C\(_2\)H\(_3\)C(O)NH\(_2\) | n      | 0   | 2.3            | 150            | <1.3 (16)      | 3.77           | 4.2            | 0.0            |

Notes. (a) n: nondetection. (b) Number of detected lines. (c) Source diameter (FWHM). (d) Rotational temperature. (e) Total column density of the molecule. x (y) means x \( \times \) 10\(^y\). (f) Correction factor that was applied to the column density to account for the contribution of vibrationally excited states, in the cases where this contribution was not included in the partition function of the spectroscopic predictions. (g) Linewidth (FWHM).

4.3. Nondetection of propionamide

We also searched for propionamide, C\(_2\)H\(_3\)C(O)NH\(_2\), which has a fully saturated alkyl group and is structurally related to acrylamide. We used the spectroscopic predictions for its vibrational ground state, \( v = 0 \), and its first vibrationally excited state, \( v = 1 \), published in \[21\]. We did not find any evidence for this molecule toward either Sgr B2(N1) or Sgr B2(N2), as illustrated in Figs. B.8–B.10 and B.11–B.13, respectively. Tables [4] and [5] report the upper limits that we derived for its column density.

\[\text{Li et al.} \ (2021)\] recently claimed the tentative detection of propionamide on the basis of the ReMoCa data set, which they accessed separately and were assigned to the ground state (here \( \theta_{\text{syn}} \)) with respect to the phase center. We also searched for propionamide toward this position using our own reduced version of the ReMoCa survey. We computed LTE synthetic spectra assuming the same source size, temperature, linewidth, and velocity as \[1\] and \[21\] and kept only the column density as a free parameter. We did not find any evidence for propionamide toward this position either. The nondetection toward this position is illustrated in Figs. B.9–B.10 and B.11–B.13 and the upper limit to its column density is reported in Table [6].

5. Discussion

5.1. Laboratory spectroscopy of acrylamide

The spectroscopic results from Sect. 3 represent a substantial improvement in the rotational spectrum of acrylamide. We have significantly extended the frequency coverage with over 8500 new transitions assigned and analyzed. The derived spectroscopic constants reproduce the assigned transitions within the experimental uncertainties on average and allow to confidently predict the rotational transitions of acrylamide over a broad range of frequencies. Of particular interest in this work was the observational window from 84.1 to 114.4 GHz in which the rotational transitions already revealed significant differences between the experimental frequencies and spectral predictions based on the original microwave work of \[20\]. For example, ground state \( K_a = 1 \leftrightarrow 0 \) transitions of the syn conformer were shifted almost by 2 MHz at the predicted uncertainty around 100 kHz. Since the syn conformer represents the ground global on the potential energy landscape of acrylamide, it is the most relevant species for observational purposes. Its ground state catalog derived from this work represents highly accurate observational reference and will be available in the Cologne Database for Molecular Spectroscopy (CDMS) to support future searches for acrylamide in space, e.g. in warm or lukewarm environments.

A comparison between the derived spectroscopic parameters of the syn conformer and those from the previous microwave study is shown in Table [1]. The most immediate conclusion to be extracted from this table is that the accuracy of these parameters is significantly improved for both the ground state and the two low-lying excited vibrational states. However, it is noticeable that while the rotational and quartic centrifugal distortion constants agree with those from \[20\], significant discrepancies are found for the sextic constants. These discrepancies are very likely attributed to incorrectly treated nuclear quadrupole hyperfine splitting, and to a lesser extent to a few misassignments in the earlier study. It has been revealed that many transitions need to be assigned to frequencies of the overlapping \( F = J \pm 1 \) hyperfine components, instead of the hyperfine-free frequencies. Rather large differences in observed minus calculated frequencies for these transitions were then artificially fit to sextic centrifugal distortion constants. However, this is no longer possible when a significantly larger data set is combined with these transitions; they clearly appear as outliers in the fit. Taking the syn conformer ground state as an example, Table [3] shows that when the incremented lines are removed from the data set of \[20\], the remaining transitions can be well fitted using two sextic constants. Their values are close to their counterparts determined solely from the data set measured in this work. Table [3] also shows that the microwave data below 60 GHz have no impact on the results of the global fit presented here. It can be explained by the fact that the access of quantum numbers of the present and previous data sets are similar. Nevertheless, the low-frequency data are maintained in the global fit for completeness.

An interesting phenomenon in this study is tunneling splitting for the skew conformer that has been observed for this species for the first time. The results of the fit for the ground state tunneling doublet are provided in Table [5] alongside the results of the previous work. In that work, the two states were analyzed separately and were assigned to the ground state (here \( 0^0 \)) and the excited C–C torsional state (here \( 0^0 \)). The spectroscopic constants are significantly improved in terms of accuracy and are consistent with those reported previously. Differences are attributable to substantially larger data set treated in this work, containing a variety of transitions. For example, only \( 14 \) \( a \)-type \( R \)-branch transitions were measured for the \( 0^0 \) state by \[20\] while over 1200 lines encompassing \( a \)-type and \( b \)-type \( R \)-branch and \( b \)-type \( Q \)-branch transitions were measured here. Although this conformer is less important for observational purposes, we made a considerable progress in the characterization of its rotational spectrum and deliver first experimental information on tunneling splitting for this species.
5.2. Comparison to other molecules in Sgr B2(N)

The nondetection of acrylamide reported in Sect. 4.2 implies that acrylamide is at least ~26 and ~6 times less abundant than acetamide toward Sgr B2(N1S) and Sgr B2(N2), respectively. For comparison, vinyl cyanide, C$_2$H$_2$CN, is about 5 times less abundant than methyl cyanide, CH$_3$CN, toward Sgr B2(N1) (Belloche et al. 2016) and a preliminary analysis of the ReMoCA survey yields a similar (slightly smaller) difference for Sgr B2(N1S). Both pairs of molecules, the amides C$_2$H$_2$C(O)NH$_2$/CH$_3$C(O)NH$_2$ and the cyanides C$_2$H$_2$CN/CH$_3$CN, share the same structural difference (an unsaturated C$_2$H$_3$ group replaced with a saturated CH$_3$ group). The upper limit to the abundance ratio C$_2$H$_2$C(O)NH$_2$/CH$_3$C(O)NH$_2$ toward Sgr B2(N2) is not constraining compared to the cyanide ratio, but toward Sgr B2(N1S), the amide ratio is at least 5 times smaller than the cyanide ratio.

5.3. Nondetection of propionamide

Some of the ALMA spectra shown in Figs. B.9 and B.10 differ from the spectra shown in Figs. 5–7 of Li et al. (2021). At least two reasons can explain these differences: first, Belloche et al. (2019) performed several iterations of self-calibration when reducing the interferometric data that were used here, while Li et al. (2021) probably did not. Second, and more importantly, the determination of the continuum level is notoriously difficult in spectra close to the confusion limit. The automatic algorithm that we used to fit the continuum level for each pixel of the data cube relies on the distribution of intensities of each pixel and removes a zeroth-order baseline (see Sect. 2.2 of Belloche et al. 2019). In contrast, Li et al. (2021) fitted first-order baselines after a manual selection of 3–5 groups of channels that seemed to be free of line emission. These different approaches can lead in some cases to different fitted continuum levels. This illustrates the additional uncertainty that arises from the continuum fitting and affects the position of the level used to assess the significance of a line detection (e.g., the 3σ level in the figures shown in Appendix B).

Several portions of the ReMoCA spectrum where we find discrepancies between the synthetic and observed spectra were not shown in Figs. 5–7 of Li et al. (2021). For instance, the transitions at 91376 MHz, 92432 MHz, 97320 MHz, 99288 MHz, or 102568 MHz in Fig. B.9, 94030 MHz or 99739 MHz in Fig. B.10. In addition, some of the lines of propionamide claimed by Li et al. (2021) as clearly detected in their Fig. 5 cannot be considered as detected in our spectra, for instance those at 92403 MHz, 92408 MHz, or 103342 MHz. Finally, Table I indicates that propionamide is at least a factor 14 times less abundant than acetamide toward Sgr B2(N1S). It would be surprising if propionamide were nearly as abundant as acetamide at the position offset to the East as claimed by Li et al. (2021). We conclude from this that there is so far no convincing evidence for the presence of propionamide in the interstellar medium.

5.4. Formation mechanisms for acrylamide and related species

In Alonso et al. (2021) we discussed the possible formation mechanisms for propiolamide in light of its nondetection, guided by findings from recent astrochemical kinetics models. Although presently no chemical networks appear to include either propiolamide, acrylamide, or propionamide, the behavior of related molecules can provide some insight into their possible behaviors. Alonso et al. (2021) proposed that propiolamide could be formed on grain surfaces at early times in the evolution of a hot core, when the gas and dust are cold and the dust-grain ice mantles are just beginning to form. At that point in time, small unsaturated hydrocarbons should be relatively abundant in the gas phase; from there, some fraction would be deposited onto the grain surfaces, where it could react further with other species. The adsorption onto the grains of C$_2$H$_3$ in particular, or its production from other species adsorbed from the gas phase, could lead to reaction with the radical NH$_2$CO to form propionamide. Alternatively, C$_2$H$_3$ could react with mobile atomic H, to produce the more stable acetylene, C$_2$H$_2$. The production on the grains of CH$_3$ could likewise lead to a reaction with NH$_2$CO to produce acetamide, with the main alternative being hydrogenation to CH$_3$. Molecules formed on the grains in this way at low temperatures would ultimately be released into the gas phase during the later hot stage of evolution.

With this in mind, Alonso et al. (2021) used the relative solid-phase abundances of C$_2$H$_2$ and CH$_4$ obtained in the models of Garrod et al. (2021) to infer the possible ratio of propionamide to acetamide on the grains. Here we extend this analysis to consider also acrylamide and propionamide, using C$_2$H$_4$ and C$_2$H$_6$ as proxies, respectively. As before, values are taken from the end-time of the cold collapse stage of evolution used in the models (technically, the final model setup of Garrod et al. 2021). We find solid-phase ratios of CH$_4$ with respect to C$_2$H$_2$, C$_2$H$_4$, and C$_2$H$_6$ of 2800, 440, and 27, respectively. This suggests that, if formed through cold addition of C$_2$H$_3$ to NH$_2$CO on grain surfaces, acrylamide should be around 440 times less abundant than acetamide. This value is in nominal agreement with the upper limit values obtained for Sgr B2(N1S) and Sgr B2(N2), and suggests that this molecule could have an abundance at least an order of magnitude below those limits. We note, however, that the ratios from the models do not consider any formation or destruction that could occur during the hot stage, nor do they take account of differences in binding energies or any associated variations in spatial arrangement in the gas phase, following thermal release from the grains.

Interestingly, the inferred ratio of acetamide to propionamide is only 27, which is indeed only a factor of two greater than the observational limit toward Sgr B2(N1S), while it is consistent with the nondetection in each source. We note also that the claim of Li et al. (2021) that propionamide is detected in Sgr B2(N) with an abundance nearly as high as acetamide is inconsistent with the abundance ratio that we infer for these species from the models.

As noted by Alonso et al. (2021), propiolamide (formed in whatever fashion) could be further hydrogenated on the dust grains all the way to propionamide. Two necessary steps in this process would be the production, and then destruction, of acrylamide, through the addition of atomic H. However, abstraction of H from any of these species or their intermediates through alternative reaction pathways with mobile atomic H could result in conversion in the other direction. Depending on the balance of activation energy barriers and branching ratios, this could therefore lead to some stable ratio between acrylamide and the other two. In fact, something like this situation occurs in the astrochemical models for the species C$_2$H$_2$, C$_2$H$_4$, and C$_2$H$_6$ themselves. One should therefore expect that the ratios derived above would already reflect this sort of relationship (any dissimilarities in activation energy barriers notwithstanding).

Alternative mechanisms for producing propiolamide, acrylamide, and propionamide, such as NH$_2$ addition to the radical C$_2$H$_3$CO, are more difficult to assess based on inference.
from the models, but they also appear plausible. Another alternative mechanism for propionamide formation would be a more direct conversion of acetamide, via the abstraction of an H atom from the methyl group (by H or some reactive radical such as OH), followed by the addition of another methyl group. Garrod et al. (2021) also invoked the reaction of methylene (CH₂) with methanol (CH₃OH) on the grains, to produce ethanol (C₂H₅OH) as well as other products. Methylene reactions might provide a route to lengthen alkyl groups in other molecules, including acetamide. This could suggest perhaps an even greater abundance for propionamide, by some unknown degree.

A more rugged test of these ideas would involve the development of a self-consistent network for all of the above species, as well as for related alkyl-group bearing molecules whose production may be competitive with the others. Application of the network to the full hot-core physical treatment would then be possible.

6. Conclusions

In the present work we conducted a detailed rotational study of acrylamide, a peptide bond bearing species, from 75 to 480 GHz. More than 6000 new rotational lines for the ground state and two excited vibrational states were measured and assigned for the most stable syn conformer. In addition to this, over 2500 lines were analyzed for the less stable skew conformer. The ground vibrational state of this conformer was observed in a doublet. We interpreted this observation as a consequence of a double-minimum potential function with a small barrier between two equivalent skew structures. A comprehensive spectral analysis provided accurate frequency predictions to search for acrylamide in Sgr B2(N). Additionally, emission lines from the related molecule propionamide were searched for in the same source. The main conclusions of these searches are following:

1. Acrylamide was not detected toward the hot molecule cores Sgr B2(N1S) and Sgr B2(N2) with ALMA. The upper limits derived for its column density imply that it is at least 26 times less abundant than acetamide toward these sources, respectively.

2. Propionamide was not detected toward Sgr B2(N1S) and Sgr B2(N2) either. It is at least 14 and 3 times less abundant than acetamide toward these sources, respectively.

3. We do not confirm either the tentative detection of propionamide recently reported in the literature toward a position offset to the East of Sgr B2(N1). We conclude from this that there is so far no convincing evidence for the presence of propionamide in the interstellar medium.

4. While acrylamide is not yet present in any astrochemical kinetics models, comparison with model results for related species suggests that acrylamide may be a few hundred times less abundant than acetamide, corresponding to a value at least an order of magnitude lower than the observational upper limits. Propionamide may be as little as a factor of two less abundant than the upper limit toward Sgr B2(N1S).

Acknowledgements. This work has been supported by the Czech Science Foundation (GACR, grant 19-25116Y). The funding is gratefully acknowledged. We thank Roman Motyjenko and Laurent Margules for sending us spectroscopic predictions for propionamide in electronic format. This paper makes use of the following ALMA data: ADS/IAU/ALMA2016.1.00074.S. ALMA is a partnership of ESO (representing its member states), NSF (USA), and NINS (Japan), together with NRC (Canada), NSC and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AU/NRAO, and NAOJ. The interferometric data are available in the ALMA archive at https://almascience.eso.org/ag/. Part of this work has been carried out within the Collaborative Research Centre 596, sub-project B3, funded by the Deutsche Forschungsgemeinschaft (DFG) – project ID 184018867. RTG acknowledges support from the National Science Foundation (grant No. AST 19-06489).

Appendix A: Complementary Tables

Table A.1 lists the measured transitions of syn acrylamide. Table A.2 lists the frequencies of normal vibrational modes of syn and skew acrylamide used to calculate the vibrational partition function. Table A.3 lists a comparison of the ground state spectroscopic constants of syn acrylamide obtained from different data sets. Table A.4 lists the measured transitions of skew acrylamide.

Appendix B: Complementary figures: Astronomical spectra

Figures B.1–B.4 illustrate the nondetection of acrylamide in its ground state, \( \nu = 0 \), and its first vibrationally excited state, \( \nu_2 = 1 \), toward Sgr B2(N1S) and Sgr B2(N2). Figures B.5–B.8 illustrate the nondetection of propionamide in its ground state, \( \nu = 0 \), and its first vibrationally excited state, \( \nu_3 = 1 \), toward Sgr B2(N1S) and Sgr B2(N2). Figures B.9 and B.10 illustrate the nondetection of propionamide in its ground state, \( \nu = 0 \), and its first vibrationally excited state, \( \nu_3 = 1 \), toward the equatorial offset position (1.58′′, −2.72′′) relative to the phase center.
Table A.1. List of the measured transitions of syn acrylamide.

Notes. (a) \(v = 0\) corresponds to \(0^+\) state and \(v = 1\) to \(0^-\) state. (b) Observed frequency. (c) Observed minus calculated frequency. (d) Uncertainty of the observed frequency. (e) Observed minus calculated frequency for blends. (f) Intensity weighting factor for blended transitions. (g) Source of the data: (1) Marstokk et al. (2000), (2) This work. This table is available in its entirety in electronic form at the CDS via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via [http://cdsweb.u-strasbg.fr/cgi-bin/qcat?J/A+A/]. A portion is shown here for guidance regarding its form and content.
Fig. B.1. Selection of transitions of acrylamide, syn-C$_2$H$_3$C(O)NH$_2$, $v = 0$ covered by the ReMoCA survey. The synthetic spectrum of syn-C$_2$H$_3$C(O)NH$_2$, $v = 0$ used to derive the upper limit to its column density is displayed in red and overlaid on the observed spectrum of Sgr B2(N1S) shown in black. The blue synthetic spectrum contains the contributions from all molecules identified in our survey so far, but not from the species shown in red. The central frequency and width are indicated in MHz below each panel. The angular resolution (HPBW) is also indicated. The y-axis is labeled in brightness temperature units (K). The dotted line indicates the 3σ noise level.

Fig. B.2. Same as Fig. B.1 but for acrylamide, syn-C$_2$H$_3$C(O)NH$_2$, $v_3 = 1$ toward Sgr B2(N1S).
Fig. B.3. Same as Fig. B.1 but for acrylamide, $\text{syn-C}_2\text{H}_3\text{C}(\text{O})\text{NH}_2$, $\nu = 0$ toward Sgr B2(N2).

Fig. B.4. Same as Fig. B.1 but for acrylamide, $\text{syn-C}_2\text{H}_3\text{C}(\text{O})\text{NH}_2$, $\nu_2 = 1$ toward Sgr B2(N2).
Fig. B.5. Same as Fig. B.1 but for propionamide, $\text{C}_2\text{H}_5\text{C(O)NH}_2$, $v = 0$ toward Sgr B2(N1S).

Fig. B.6. Same as Fig. B.1 but for propionamide, $\text{C}_2\text{H}_5\text{C(O)NH}_2$, $v_30 = 1$ toward Sgr B2(N1S).
Fig. B.7. Same as Fig. B.1 but for propionamide, C$_2$H$_5$C(O)NH$_2$, $v = 0$ toward Sgr B2(N2).
Fig. B.8. Same as Fig. B.1 but for propionamide, C₃H₅C(O)NH₂, v₀ = 1 toward Sgr B2(N2).
Fig. B.9. Selection of transitions of propionamide, $\text{C}_2\text{H}_5\text{C}(\text{O})\text{NH}_2$, $v = 0$ covered by the ReMoCA survey. The synthetic spectrum of $\text{C}_2\text{H}_5\text{C}(\text{O})\text{NH}_2$, $v = 0$ used to derive the upper limit to its column density is displayed in red and overlaid on the black spectrum observed toward the equatorial offset position (1.58′, −2.72′) relative to the phase center. The central frequency and width are indicated in MHz below each panel. The angular resolution (HPBW) is also indicated. The $y$-axis is labeled in brightness temperature units (K). The dotted line indicates the $3\sigma$ noise level.
Fig. B.9. continued.
Fig. B.10. Same as Fig. B.9 but for propionamide, $\text{C}_2\text{H}_5\text{C(O)NH}_2$, $v_{30} = 1$.
