Frequency-Sliding Generalized Cross-Correlation: A Sub-band Time Delay Estimation Approach

Maximo Cobos, Senior Member, IEEE, Fabio Antonacci, Senior Member, IEEE, Luca Comanducci, Student Member, IEEE, and Augusto Sarti, Senior Member, IEEE

Abstract—The generalized cross correlation (GCC) is regarded as the most popular approach for estimating the time difference of arrival (TDOA) between the signals received at two sensors. Time delay estimates are obtained by maximizing the GCC output, where the direct-path delay is usually observed as a prominent peak. Moreover, GCCs play also an important role in steered response power (SRP) localization algorithms, where the SRP functional can be written as an accumulation of the GCCs computed from multiple sensor pairs. Unfortunately, the accuracy of TDOA estimates is affected by multiple factors, including noise, reverberation and signal bandwidth. In this paper, a sub-band approach for time delay estimation aimed at improving the performance of the conventional GCC is presented. The proposed method is based on the extraction of multiple GCCs corresponding to different frequency bands of the cross-power spectrum phase in a sliding-window fashion. The major contributions of this paper include: 1) a sub-band GCC representation of the cross-power spectrum phase that, despite having a reduced temporal resolution, provides a more suitable representation for estimating the true TDOA; 2) such matrix representation is shown to be rank one in the ideal noiseless case, a property that is exploited in more adverse scenarios to obtain a more robust and accurate GCC; 3) we propose a set of low-rank approximation alternatives for processing the sub-band GCC matrix, leading to better TDOA estimates and source localization performance. An extensive set of experiments is presented to demonstrate the validity of the proposed approach.

Index Terms—Time delay estimation, GCC, SVD, weighted SVD, sub-band processing, SRP-PHAT.

I. INTRODUCTION

T
ime delay estimation (TDE) refers to finding the time differences-of-arrival (TDOAs) between signals received at an array of sensors. Traditionally, TDE has played an important role in many location-aware systems, including radar, sonar, wireless systems, sensor calibration or seismology. In acoustic signal processing, TDE is essential for localizing and tracking acoustic sources [1], [2]. Automatic camera steering, speaker localization or speech enhancement systems are application examples strongly relying on TDE [3].

The generalized cross-correlation (GCC), originally proposed by Knapp and Carter in their 1976 seminal paper [4], is still today the most popular technique for TDE. By using GCCs, the TDOA between two signals is estimated as the time lag that, applied to one of the signals, maximizes the cross-correlation between filtered versions of such signals. In this context, the GCC may consider different weighting functions (filters) characterized by a particular behavior [5], [6], [7]. Roth, smoothed coherence transform, Eckart or Hannan-Thomson (maximum likelihood) are examples of such weighting schemes [4], [8]. Nonetheless, the GCC with phase transform (GCC-PHAT), has been repeatedly shown to be the best performing alternative in noisy and reverberant scenarios [9], [10], [11]. The present work is particularly focused on PHAT weighting, thus, the terms GCC and GCC-PHAT will be used indistinctly throughout this paper.

Since the GCC was first proposed, many approaches have appeared to ameliorate the robustness of TDE techniques, with improvements that are mostly achieved by exploiting the spatial diversity provided by more than two microphones [12], [13], [14], blind channel estimation [15], [16], modified GCC weightings [17], or the incorporation of some a priori information [18], [19]. In contrast to such methods, this paper proposes a novel sub-band approach to TDE with two sensors which is not directly categorized within the above processing improvements. Concretely, the method is based on the exploration of the cross-power spectrum phase by following a sliding window approach, obtaining a set of sub-band GCCs that encode the contribution of different frequency bands to the estimated TDOA. The resulting sub-band GCC matrix is shown to be rank-one for a full-band signal in the noiseless single-path case. This fact is exploited to obtain a robust GCC in adverse scenarios, proposing low-rank approximations of the sub-band GCC matrix that ultimately lead to better estimation accuracy, reduced level of spurious peaks and lower probability of anomalous estimates.

The rest of the paper is structured as follows. Section II summarizes the background concerning GCC-based TDOA estimation. Section III presents and the frequency-sliding GCC (FS-GCC) representation. Section IV discusses our proposed methods for TDE based on the FS-GCC. The experimental evaluation is in Section V. Finally, the conclusions of this work are summarized in Section VI.

II. TIME DELAY ESTIMATION

This section summarizes the conventional GCC approach for TDE. To this end, the ideal anechoic model is first presented, discussing the main problems arising in realistic acoustic conditions.
A. Anechoic Signal Model

Let us consider a pair of sensors with spatial coordinates given by column vectors \( \mathbf{m}_1, \mathbf{m}_2 \in \mathbb{R}^3 \) and an emitting acoustic source located at \( s \in \mathbb{R}^3 \). The time difference-of-arrival (TDOA) measured in samples is defined as

\[
\tau_{12} \triangleq \frac{\|s - \mathbf{m}_1\| - \|s - \mathbf{m}_2\|}{c} f_s = \eta_1 - \eta_2, \tag{1}
\]

where \( c \) is the wave propagation speed, \([\cdot]\) denotes the rounding operator and \( f_s \) is the sampling frequency. The terms \( \eta_1 \) and \( \eta_2 \) represent the time of flight (TOF) of the sound to the sensors in samples.

Assuming an anechoic scenario, the signals received by the two sensors can be modeled as

\[
x_m[n] = \beta_m s[n - \eta_m] + w_m[n], \quad m = 1, 2, \tag{2}
\]

where \( \beta_m \in \mathbb{R}_+ \) is a positive amplitude decay factor, \( s[n] \) is the source signal and \( w_m[n] \) is an additive noise term. In the discrete-time Fourier transform (DTFT) domain, the sensor signals can be written as

\[
X_m(\omega) = \beta_m S(\omega) e^{-j\omega \eta_m} + W_m(\omega), \quad m = 1, 2, \tag{3}
\]

where \( S(\omega), W_m(\omega) \in \mathbb{C} \) are the DTFTs of the source signal and the noise signal, respectively, and \( j = \sqrt{-1} \).

B. Generalized Cross-Correlation

The GCC of a pair of sensor signals is defined as the inverse Fourier transform of the weighted cross-power spectrum, i.e.

\[
R_{12}[\tau] \triangleq \frac{1}{2\pi} \int_{-\pi}^{\pi} \Psi_{12}(\omega) e^{j\omega \tau} d\omega = F^{-1} \{ \Psi_{12}(\omega) \}, \tag{4}
\]

where \( \tau \in \mathbb{Z} \) represents time delay and \( \Psi_{12}(\omega) \in \mathbb{C} \) represents the phase transform (PHAT) cross-power spectrum:

\[
\Psi_{12}(\omega) \triangleq \frac{X_1(\omega)X_2^*(\omega)}{|X_1(\omega)X_2^*(\omega)|}, \tag{5}
\]

where \((\cdot)^*\) denotes complex conjugation. Note that, in the ideal anechoic and noiseless case, \( \Psi_{12}(\omega) = \frac{\beta_1 \beta_2 |S(\omega)|^2}{|\beta_1 \beta_2 S(\omega)|^2} e^{-j\omega \tau_{12}} = e^{-j\omega \tau_{12}} \), leading to

\[
R_{12}[\tau] = F^{-1} \{ e^{-j\omega \tau_{12}} \} = \delta[\tau - \tau_{12}], \tag{6}
\]

where \( \delta[\cdot] \) is the Kronecker delta function. Therefore, the ideal GCC-PHAT for a full-band source signal will show a unit impulse located at the true TDOA. This motivates the use of the following estimator for time-delay estimation over signals acquired by a pair of sensors:

\[
\hat{\tau}_{12} = \arg \max_{\tau} R_{12}[\tau]. \tag{7}
\]

It is important to remark that the measured time delay is an integral multiple of the sampling period. Note, however, that a finer resolution can be achieved by interpolating between consecutive samples of the GCC function if necessary.

C. Problems in Realistic Scenarios

It is well-known that several problems arise when using GCC-PHAT for estimating the TDOA in realistic scenarios. Indeed, TDOA measurements are very sensitive to reverberation, noise, and the presence of potential interferers:

- In reverberant environments, for certain locations and orientations of the source signal, the peak of the GCC relative to a reflective path could overcome that of the direct path.
- In noisy scenarios, for some time instants, the noise level could exceed that of the signal, making the estimated TDOA unreliable.
- Peaks corresponding to the direct path, reflections or combinations of interfering signals may also lead to errors when estimating the TDOA of a target source.

The above issues can be even more problematic when the spectral characteristics of the target source lead to a reduced signal-to-noise ratio (SNR) at some frequency bands [20]. For example, the phase information will be very noisy at those frequency bands where there is not signal information at all. In this context, consider the (normalized) GCCs shown in Figure 1 for full-band, low-pass and pass-band signals. As it can be observed, the noisy phase introduces many spurious peaks that can cause anomalous TDOA estimates. Although noisy frequency bands could be filtered out to obtain a cleaner GCC (last column of Fig. 1), knowing beforehand the best frequency range accommodating the source signal is not always straightforward. Moreover, the rippling GCCs resulting from pass-band signals complicate substantially source localization tasks in adverse conditions [20].

III. FREQUENCY-SLIDING GENERALIZED CROSS-CORRELATION

This section proposes a frequency-sliding GCC-PHAT method that generalizes the filtering approach discussed in the last section with the aim of obtaining a robust GCC representation. This representation will be useful to explore the likelihood of different frequency bands contributing to a direct-path delay estimate.

A. Sub-band GCCs

Let us define the sub-band GCC for an arbitrary frequency band \( l \) as

\[
R_{12}[\tau, l] \triangleq \frac{1}{2\pi} \int_{-\pi}^{\pi} \Psi_{12}(\omega + \omega_l) \Phi(\omega) e^{j\omega \tau} d\omega = F^{-1} \{ \Psi_{12}(\omega + \omega_l) \Phi(\omega) \}, \tag{8}
\]

where \( \omega_l \) is the frequency offset corresponding to band \( l \). The function \( \Phi(\omega) \in \mathbb{R} \) is a symmetric frequency-domain window, centered at \( \omega = 0 \) with frequency support \( B_F \in [0, \pi] \), i.e. \( \Phi(\omega) = 0 \) for \( |\omega| \geq B_F \).

The effect of the window and the cross-power spectrum can be separated as follows:

\[
R_{12}[\tau, l] = F^{-1} \{ \Psi_{12}(\omega + \omega_l) \} \Phi(\omega) = e^{-j\omega \tau} R_{12}[\tau] \Phi(\omega) = e^{-j\omega \tau} \phi[\tau], \tag{9}
\]

where \( \phi[\tau] = \Phi(\omega) e^{j\omega \tau} \).

It is well-known that several problems arise when using GCC-PHAT for estimating the TDOA in realistic scenarios. Indeed, TDOA measurements are very sensitive to reverberation, noise, and the presence of potential interferers:

- In reverberant environments, for certain locations and orientations of the source signal, the peak of the GCC relative to a reflective path could overcome that of the direct path.
- In noisy scenarios, for some time instants, the noise level could exceed that of the signal, making the estimated TDOA unreliable.
- Peaks corresponding to the direct path, reflections or combinations of interfering signals may also lead to errors when estimating the TDOA of a target source.

The above issues can be even more problematic when the spectral characteristics of the target source lead to a reduced signal-to-noise ratio (SNR) at some frequency bands [20]. For example, the phase information will be very noisy at those frequency bands where there is not signal information at all. In this context, consider the (normalized) GCCs shown in Figure 1 for full-band, low-pass and pass-band signals. As it can be observed, the noisy phase introduces many spurious peaks that can cause anomalous TDOA estimates. Although noisy frequency bands could be filtered out to obtain a cleaner GCC (last column of Fig. 1), knowing beforehand the best frequency range accommodating the source signal is not always straightforward. Moreover, the rippling GCCs resulting from pass-band signals complicate substantially source localization tasks in adverse conditions [20].

This section proposes a frequency-sliding GCC-PHAT method that generalizes the filtering approach discussed in the last section with the aim of obtaining a robust GCC representation. This representation will be useful to explore the likelihood of different frequency bands contributing to a direct-path delay estimate.

A. Sub-band GCCs

Let us define the sub-band GCC for an arbitrary frequency band \( l \) as

\[
R_{12}[\tau, l] \triangleq \frac{1}{2\pi} \int_{-\pi}^{\pi} \Psi_{12}(\omega + \omega_l) \Phi(\omega) e^{j\omega \tau} d\omega = F^{-1} \{ \Psi_{12}(\omega + \omega_l) \Phi(\omega) \}, \tag{9}
\]

where \( \omega_l \) is the frequency offset corresponding to band \( l \). The function \( \Phi(\omega) \in \mathbb{R} \) is a symmetric frequency-domain window, centered at \( \omega = 0 \) with frequency support \( B_F \in [0, \pi] \), i.e. \( \Phi(\omega) = 0 \) for \( |\omega| \geq B_F \).

The effect of the window and the cross-power spectrum can be separated as follows:

\[
R_{12}[\tau, l] = F^{-1} \{ \Psi_{12}(\omega + \omega_l) \} \Phi(\omega) = e^{-j\omega \tau} R_{12}[\tau] \Phi(\omega) = e^{-j\omega \tau} \phi[\tau], \tag{10}
\]

where \( \phi[\tau] = \Phi(\omega) e^{j\omega \tau} \).
or equivalently,

\[ R_{12}[\tau, l] = \mathcal{F}^{-1} \{ \Psi_{12}(\omega) \Phi(\omega - \omega_l) \} e^{-j\omega_l \tau}, \]

\[ = \left( R_{12}[\tau] * \phi[\tau] e^{j\omega_l \tau} \right) e^{-j\omega_l \tau}, \tag{11} \]

where \( \phi[\tau] \in \mathbb{R} \) represents the inverse Fourier transform of the spectral window \( \Phi(\omega) \) and \(*\) denotes convolution. For example, if \( \Phi(\omega) \) is selected to be a rectangular window, i.e. \( \Phi(\omega) = \text{rect} \left( \frac{\omega}{2\pi} \right) \), the sub-band GCC would be given by

\[ R_{12}[\tau, l] = \left( e^{-j\omega_l \tau} R_{12}[\tau] \right) \frac{\sin (B_\Phi \tau)}{\pi \tau}. \tag{12} \]

A frequency-sliding sub-band GCC can be obtained by sweeping the cross-power spectrum phase over (possibly) overlapping frequency bands:

\[ \omega_l = l M_\Phi, \quad l = 0, \ldots, L - 1, \tag{13} \]

where \( M_\Phi \) is the frequency hop. The number of bands \( L \) can be conveniently chosen to cover those frequencies up to the Nyquist limit:

\[ L = \left\lfloor \frac{\pi - B_\Phi + M_\Phi}{M_\Phi} \right\rfloor. \tag{14} \]

An interpretation of such sliding operation is shown in Figure 2. As given by Eq. (11), the sub-band GCCs can be interpreted as the product of \( \Psi_{12}(\omega) \) with a shifted version of \( \Phi(\omega) \) to \( \omega_l \), shifted back in frequency to zero before taking the inverse Fourier transform.

### B. Frequency-Sliding GCC Matrix

In practice, sub-band GCCs are extracted considering the discrete Fourier transform (DFT) of the microphone signals \( x_m[n] \):

\[ \mathbf{X}_m = [X_m[0], X_m[1], \ldots, X_m[N-1]]^T, \quad m = 1, 2, \tag{15} \]

where the elements of \( \mathbf{X}_m \in \mathbb{C}^N \) are the coefficients \( X_m[k] \) corresponding to the discrete frequencies \( \omega_k = k \frac{2\pi}{N} \). Similarly, consider the vector \( \Phi \) containing the discrete-frequency samples \( \Phi[k] = \Phi(\omega_k) \) of the selected spectral window

\[ \Phi = [\Phi[0], \Phi[1], \ldots, 0, \ldots, 0, \ldots, \Phi[N-1]]^T \in \mathbb{R}^N, \tag{16} \]

symmetrically padded with zeros to contain only \( B = \left\lfloor \frac{2B_\Phi N}{M_\Phi} \right\rfloor \) non-zero elements.

The sub-band GCC vectors \( \mathbf{r}_l \in \mathbb{C}^N \) are obtained by taking the inverse DFT of the windowed PHAT spectrum, i.e.

\[ \mathbf{r}_l = [r_l[0], r_l[1], \ldots, r_l[N-1]]^T, \quad l = 0, \ldots, L - 1, \tag{17} \]

Fig. 2. Interpretation of the frequency-sliding GCC.
where $M = \left\lceil M_{\phi} \frac{N}{2} \right\rceil$ is the discrete frequency hop.

The frequency-sliding GCC (FS-GCC) matrix is constructed by stacking all the sub-band GCC vectors together, i.e.

$$R_{12} = [r_0, r_1, \ldots, r_{L-1}] \in \mathbb{C}^{N \times L},$$

noting that

$$R_{12}[n,l] = \begin{cases} R_{12}[n,l], & n = 0, \ldots, N/2 - 1, \\ R_{12}[-n,l], & n = N/2, \ldots, N - 1. \end{cases}$$

C. Ideal Sub-band GCC Model

To get an insight into the properties underlying the presented FS-GCC representation, let us start by considering the ideal full-band cross-power spectrum of Eq. (6). $\Psi_{12}(\omega) = e^{-j\omega\tau_{12}}$. By inserting Eq. (7) into Eq. (10), the ideal sub-band GCCs (denoted with a tilde) are given by

$$\tilde{R}_{12}[\tau,l] = e^{-j\omega\tau_{12}} [\phi[\tau - \tau_{12}] \ast \phi]\] = e^{-j\omega\tau_{12}} \phi[\tau - \tau_{12}], \quad l = 1, \ldots, L. \quad (21)$$

By analyzing the above result, some interesting observations arise:

- The magnitudes of the sub-band GCCs are independent of the selected frequency offset $\omega$, and correspond to the inverse Fourier transform of the sub-band analysis window centered at the true TDOA: $|\tilde{R}_{12}[\tau,l]| = |\phi[\tau - \tau_{12}]|$, $\forall l$. \quad (22)

- The maximum value of $|\tilde{R}_{12}[\tau,l]|$ is located at $\tau = \tau_{12}$ for every sub-band, $l = 0, \ldots, L - 1$.

- The peak width at the true TDOA, as well as the level of its side lobes, depends on the selected type of window $\Phi(\omega)$ and its frequency support $B_{\Phi}$.

- Since the spectral window is real and even, $\tilde{R}_{12}[\tau,l]$ is also real and even. Then, the phase pattern of the set of sub-band GCCs corresponds to a downsampled version of $\angle (\Psi_{12}(\omega))$, modulated by the sign of $\phi[\tau]$.

- The full-band conventional GCC can be recovered from the sub-band GCCs if the constant overlap-add (COLA) property is fulfilled.

Consequently, the FS-GCC matrix will present the following features:

- The columns of $R_{12}$ correspond to the window response shifted to the true TDOA and multiplied by a different complex number, i.e.

$$\tilde{r}_l = e^{-j\omega\tau_{12}} \phi_{12},$$

where $\phi_{12} \in \mathbb{R}^N$ is a vector containing $N$ samples of the shifted window response:

$$\phi_{12} = \phi[n - \tau_{12}] = [\phi[0 - \tau_{12}] \ldots \phi[N/2 - 1 - \tau_{12}] \ldots \phi[-N/2 - \tau_{12}] \ldots \phi[-1 - \tau_{12}]]^T. \quad (24)$$

- The ideal FS-GCC matrix, $\tilde{R}_{12}$, can be expressed as an outer product, resulting in a rank-one matrix:

$$\tilde{R}_{12} = \phi_{12} e^H,$$ \quad (25)

where $e \triangleq [e^{j\omega \tau_{12}}, \ldots, e^{j\omega L - 1\tau_{12}}]^T \in \mathbb{C}^L$ and $(\cdot)^H$ denotes the conjugate transpose operator.

This last observation will be used to estimate robustly the time-delay in realistic cases (noisy and/or reverberant scenarios with reduced/varying bandwidth signals).

D. Noisy Sub-band GCC Model

In a more general case, the columns of the FS-GCC matrix will contain different amounts of noise depending on the SNR characterizing the different sub-bands, i.e.

$$r_l = \alpha_l \tilde{r}_l + (1 - \alpha_l) n_l, \quad l = 0, \ldots, L - 1,$$

where $n_l \in \mathbb{C}^N$ models the GCC noise component of the $l$-th sub-band, and $\alpha_l \in [0, 1]$ is a scalar that balances the contribution of the noise in the $l$-th sub-band. Since the noise vectors in the frequency domain have a normalized magnitude spectrum given by the spectral window in the noise, it follows from Parseval’s theorem that

$$n_l^H n_l = \|n_l\|^2 = \|\phi_l\|^2 = \int_{-\pi}^{\pi} \Phi(\omega)^2 d\omega. \quad (27)$$

Similarly, the $R_{12}$ matrix can be expressed as:

$$R_{12} = \tilde{R}_{12} G + N(I - G),$$

where $I \in \mathbb{R}^{L \times L}$ is the identity matrix, $N \in \mathbb{C}^{N \times L}$ is the matrix containing all the noise vectors, i.e.

$$N = [n_0, n_1, \ldots, n_{L-1}],$$

and $G \in \mathbb{R}^{L \times L}$ is the diagonal matrix

$$G = \begin{bmatrix} \alpha_0 & 0 & \ldots & 0 \\ 0 & \alpha_1 & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & \alpha_{L-1} \end{bmatrix}. \quad (30)$$

In contrast to the ideal case, the non-ideal FS-GCC matrix $R_{12}$ will have rank $L$ unless more than one of the diagonal entries $\alpha_l$ are equal to 1.

E. Examples

Figures 4(a-c) show the resulting FS-GCCs for the three basic types of signals analyzed in Figure 4: A Hann spectral window with a frequency support of $B = 64$ bins ($B_{\phi} = 0.1$) and 50% overlap was used, resulting in $L = 32$ sub-bands. As it can be observed, the first row corresponding to the full-band signal shows a peak perfectly aligned across all the analyzed bands and centered at the true TDOA. Due to the use of the Hann window, the side-lobes are considerably small. The other rows corresponding to the low-pass and pass-band signals show also a similar pattern, but only at those sub-bands where the SNR is sufficient to preserve the phase information of the cross-power spectrum. The noise over the
Fig. 3. Sub-band GCCs obtained for the synthetic examples shown in Fig. 1 and for a real speech signal: (a) full-band; (b) low-pass; (c) pass-band. (d) Examples for three different frames of a speech signal.

rest of sub-bands can be also identified, showing that no useful delay information can be extracted from other frequencies.

An example considering a more realistic signal can be observed in Figure 3(d), corresponding to three different time frames ($N = 2048$ samples, $f_s = 44.1$ kHz) of a male speech signal. In this case, $B$ has been set to 128 bins, resulting in a narrower peak. As observed, the useful bandwidth of common audio signals as speech may change considerably with time and the FS-GCC representation shows clearly which frequency bands are actively contributing to a reliable time delay estimate. Note also that the last speech example shows a bandwidth that is considerably narrower than the other two, which makes TDE more difficult in this case.

While the full-band ideal case results in a high peak continuously present over all the frequency-bands leading to a rank one matrix, in a general case, noise and reflections will interact with the linear phase component corresponding to the direct-path delay, producing a matrix with full column rank. TDE from the FS-GCC matrix should be therefore oriented towards the extraction of the reliable components of $R_{12}$, discarding properly the information from noisy bands.

IV. LOW-RANK APPROXIMATIONS OF THE FS-GCC MATRIX

This section exploits the properties of the presented sub-band FS-GCC representation by proposing a low-rank approximation framework based on singular value decompositions. Such low-rank representations will be shown to provide a robust GCC for TDE in adverse conditions.

A. Singular Value Decomposition

A low-rank approximation of $R_{12}$ can be obtained by solving

$$\min_{\hat{R}_{12}} \| R_{12} - \hat{R}_{12} \|_F, \quad \text{subject to } \text{rank}(\hat{R}_{12}) \leq r \quad (31)$$

where $r$ is the rank of the approximating matrix $\hat{R}_{12}$, and $\| \cdot \|_F$ denotes the Frobenius norm. The problem has an analytic solution in terms of the singular value decomposition (SVD) of $R_{12}$, as given by the Eckart-Young-Mirsky theorem. Let us factorize $R_{12}$ as

$$R_{12} = U\Sigma V^H,$$  \quad (32)

where $U \in \mathbb{C}^{N \times L}$ is the matrix containing the left singular vectors, $\Sigma \in \mathbb{R}^{L \times L}$ is the diagonal matrix containing the ordered singular values and $V \in \mathbb{C}^{L \times L}$ is the matrix containing the right singular vectors. The SVD can be interpreted as a decomposition of a matrix into a weighted, ordered sum of separable matrices as follows:

$$R_{12} = \sum_i R_{12}^{(i)} = \sum_i \sigma_i u_i v_i^T,$$  \quad (33)

where $u_i$ and $v_i$ are the $i$-th columns of the corresponding SVD matrices and $\sigma_i$ are the ordered singular values. The
particular rank-\(r\) matrix that best approximates \(R_{12}\) is given by
\[
R'_{12} = \sum_{i=1}^{r} \sigma_i u_i v_i^T. \tag{34}
\]

Another interpretation of the above SVD approximation can be made in terms of Principal Component Analysis (PCA). In fact, the matrix \(R_{12}\) can be thought of as a matrix containing \(N\) samples of \(L\) variables. The covariance matrix is proportional to
\[
C = R_{12}^H R_{12} = V \Sigma U^H U \Sigma V^H = V \Sigma^2 V^H, \tag{35}
\]
meaning that \(V\) contains the principal directions of the data. The projections on the principal axes, known as principal components, are given by \(R_{12} V = U \Sigma V^H\). The multiplication of the first \(r\) principal components by the corresponding principal axes yields the rank \(r\) approximation \(R'_{12} = \sum_{i=1}^{r} \sigma_i u_i v_i^T\).

\[B.\text{ Separation of GCC Components}\]

Let us assume that the sub-band GCC matrix can be expressed by two separable components: a target-path delay component and a noise component. Moreover, as it will be later discussed in Section [IV.C], we assume that the direct-path component is the one contributing to the greatest singular value, while the noise component is obtained by the addition of the rest of separable matrices, i.e.
\[
R_{12}^{\text{target}} = R_{12}^{(1)} = \sigma_1 u_1 v_1^T, \tag{36}
\]
\[
R_{12}^{\text{noise}} = \sum_{i=2}^{r} \sigma_i u_i v_i^T. \tag{37}
\]

An example decomposition applied over the three speech frames discussed in the previous section is shown in Figure 2. Note that the true delay is substantially enhanced by the target delay component of the SVD decomposition. The third speech frame (row 3) is the one having the noisiest FS-GCC, due to its reduced SNR.

\[C.\text{ Target GCC Extraction}\]

The singular values and the left singular vectors correspond, respectively, to the square-root of the eigenvalues and the orthonormal eigenvectors of \(R_{12} R_{12}^H\). In the ideal case, taking into account Eq. (25):
\[
\hat{R}_{12} R_{12}^H = \phi_{12} e^{H} e \phi_{12}^H = L \phi_{12} \phi_{12}^H \tag{38}
\]
is singular, with \((L-1)\) zero eigenvalues and one non-zero eigenvalue \(\lambda = L \phi_{12}^H \phi_{12} = L \|\phi\|^2\) associated to the eigenvector \(\phi_{12}\). This means that such eigenvector should contain the information of the TDOA-shifted window of Eq. (24).

In the general noisy case, the left singular vectors will be eigenvectors of
\[
R_{12} R_{12}^H = \left(\hat{R}_{12} G + N(I-G)\right) \left(\hat{R}_{12} G + N(I-G)\right)^H = \left(\sum_{l=0}^{L-1} \alpha_l^2 \right) \phi_{12} \phi_{12}^H + \sum_{l=0}^{L-1} (1 - \alpha_l)^2 n_l n_l^H + \sum_{l=0}^{L-1} (\alpha_l - \alpha_l^2) e^{j\omega_l \tau_{12}} n_l \phi_{12}^H + \sum_{l=0}^{L-1} (\alpha_l - \alpha_l^2) e^{-j\omega_l \tau_{12}} \phi_{12} n_l^H. \tag{39}
\]

It is readily seen that when \(G = I\), i.e. when no noise is present in any of the sub-bands, the result is the same as that of Eq. (38), given by the first term of Eq. (39). The second term, which depends on the noise components of the GCC, is a rank \(L\) hermitian matrix with \(L\) non-zero real eigenvalues. The third term is a rank-one matrix with a non-zero eigenvalue associated to a noise-dependent complex eigenvector. Finally, the fourth term is another rank-one matrix, with one non-zero eigenvalue related to the eigenvector \(\phi_{12}\).

As a simplified example, a matrix \(G\) with \(L_g\) ones and \((L - L_g)\) zeros in its diagonal, i.e. either with perfect sub-bands or completely noisy sub-bands, will only contain the first (target) rank-one term and the second (noise) term with rank \((L - L_g)\). The eigenvalue corresponding to the target term will be \(L_g \|\phi\|^2\), while the sum of the eigenvalues of the second term will be \((L - L_g) \|\phi\|^2\). In most practical cases, the greatest singular value is expected to be dominated by the target rank-one component, which justifies the use of a rank one approximation in terms of \(u_1\).

Taking the above discussion into account, under high SNR conditions, the first left singular vector should be dominated by the first term of Eq. (39), corresponding to the eigenvector \(\phi_{12}\). Since such eigenvector should be ideally real, we take the real part of \(u_1\), \(\Re\{u_1\}\), and set its norm to \(\|\phi\|\):
\[
\phi_{12} = \|\phi\| \frac{\Re\{u_1\}}{\|\Re\{u_1\}\|} \text{sign}(\Re\{u_1[\gamma]\}), \tag{40}
\]
where \(\Re\{u_1[\gamma]\}\) is the element of \(\Re\{u_1\}\) having the maximum absolute value, i.e.
\[
\gamma = \arg \max_n |\Re\{u_1[n]\}|. \tag{41}
\]

Note that this last equation and the \(\text{sign}(\cdot)\) function in Eq. (40) are used as a criterion for solving the singular vector sign ambiguity (both \(u_1\) and \(-u_1\) are eigenvectors of \(R_{12} R_{12}^H\), forcing a positive peak in \(\phi_{12}\)). The estimated TDOA is given by the position of such peak:
\[
\hat{\tau}_{12} = \arg \max_n \hat{\phi}_{12}[n]. \tag{42}
\]

Fig. 3(b) shows the recovered GCCs from the target SVD decomposition (SVD FS-GCC), \(\hat{\phi}_{12}\), for the speech frames shown in the previous examples.
D. Weighted Low-Rank Approximation

The Frobenius norm weights uniformly all the elements of the approximation error \( \| \mathbf{R}_{12} - \hat{\mathbf{R}}_{12} \|_F \). However, it can be very useful in practice to assign particular weights to the different sub-band GCCs, based on some defined confidence measure. Therefore, weighted low-rank approximations are of interest here, where the problem is now to solve \([21]\)

\[
\min_{\mathbf{A}, \mathbf{B}} \| \mathbf{R}_{12} - \hat{\mathbf{R}}_{12} \|_F \quad \text{subject to} \quad \text{rank}(\hat{\mathbf{R}}_{12}) \leq r, \tag{43}
\]

where \( \mathbf{W} \in \mathbb{R}^{N \times L} \) is a weight matrix with non-negative weights and \( \odot \) denotes the Hadamard product operator. The above equation is equivalent to solving a weighted Frobenius norm, where a given weight is assigned to each entry of the matrix \( \mathbf{R}_{12} \), i.e.

\[
\| \mathbf{R}_{12} - \hat{\mathbf{R}}_{12} \|_F = \sum_{n=1}^{N} \sum_{l=1}^{L} w_{n,l} \left( \mathbf{R}_{12}[n,l] - \hat{\mathbf{R}}_{12}[n,l] \right)^2, \tag{44}
\]

where \( w_{n,l} \) are the weight entries of the matrix \( \mathbf{W} \). To address the problem, it is useful to consider the decomposition \( \mathbf{R}_{12} = \mathbf{A}\mathbf{B}^H \), where \( \mathbf{A} \in \mathbb{C}^{N \times r} \) and \( \mathbf{B} \in \mathbb{C}^{L \times r} \). Since any rank-\( r \) matrix can be decomposed in such a way, and any pair of such matrices yields a rank-\( r \) matrix, we can think of the problem as an unconstrained minimization problem over pairs of matrices \( (\mathbf{A}, \mathbf{B}) \) with the minimization objective:

\[
\min_{\mathbf{A}, \mathbf{B}} \| (\mathbf{R}_{12} - \mathbf{A}\mathbf{B}^H) \|_F, \tag{45}
\]

Such decomposition is not unique. For any invertible \( \mathbf{M} \in \mathbb{C}^{r \times r} \), the pair \( (\mathbf{A}, \mathbf{B} \mathbf{M}^{-1}) \) provides a factorization equivalent to \( \mathbf{A}\mathbf{B}^H \). In particular, any (non-degenerate) solution \( (\mathbf{A}, \mathbf{B}) \) can be orthogonalized to a (non-unique) equivalent orthogonal solution \( \hat{\mathbf{A}} = \mathbf{A}\mathbf{M}^{-1}, \hat{\mathbf{B}} = \mathbf{B} \mathbf{M}^{-1} \) such that \( \hat{\mathbf{B}}^H\hat{\mathbf{B}} = \mathbf{I} \) and \( \hat{\mathbf{A}} \hat{\mathbf{B}}^H \) is a diagonal matrix. As discussed in the previous section, the solution in the unweighted case would be obtained in terms of the truncated SVD. In our particular application, the weight matrix can be restricted to follow the specific structure:

\[
\mathbf{W} = \begin{bmatrix}
w_0 & w_1 & \cdots & w_{L-1} \\
w_0 & w_1 & \cdots & w_{L-1} \\
\vdots & \vdots & \ddots & \vdots \\
w_0 & w_1 & \cdots & w_{L-1}
\end{bmatrix} = \mathbf{1}^{w^T}, \tag{46}
\]

where \( \mathbf{1} \) is a column vector of length \( N \) and \( w = [w_0, w_1, \ldots, w_{L-1}]^T \) is a vector containing confidence weights \( w_l \in [0,1] \) assigned to each of the \( L \) sub-bands. Under such case, due to the structure of \( \mathbf{W} \), the problem of Eq. (43) can be rewritten as the factorization of a modified matrix \( \mathbf{R}_{w12} \) \([22]\):

\[
\min_{\mathbf{A},b_w} \| (\mathbf{R}_{w12} - \mathbf{A}\mathbf{B}^H) \|_F, \tag{47}
\]

where

\[
\mathbf{R}_{w12} = \mathbf{R}_{12} \mathbf{W}, \tag{48}
\]

\[
\mathbf{B}_w = \mathbf{W} \mathbf{B}, \tag{49}
\]

\[
\mathbf{W} = \text{diag}(w_1, w_2, \ldots, w_L). \tag{50}
\]

By applying SVD factorization to \( \mathbf{R}_{w12} \) and conveniently truncating to the largest \( r \) singular values, the estimates of \( \mathbf{A} \) and \( \mathbf{B}_w \) are obtained as \( \mathbf{A} = \mathbf{U}\Sigma^{1/2} \) and \( \mathbf{B}_w = \mathbf{V}\Sigma^{1/2} \), where \( \Sigma \) is the truncated singular value matrix. The rank-\( r \) approximation is therefore recovered as:

\[
\mathbf{R}_{12} = \hat{\mathbf{A}}\hat{\mathbf{B}}^H = \hat{\mathbf{A}}(\mathbf{W}^{-1}\mathbf{B}_w)^H. \tag{51}
\]

Taking again into consideration that the noiseless sub-band GCC matrix is rank one, the target and noise components are extracted as:

\[
\mathbf{R}_{12}^{\text{target}} = \hat{\mathbf{a}}_1\hat{\mathbf{b}}_1^H, \tag{52}
\]

\[
\mathbf{R}_{12}^{\text{noise}} = \sum_{i=2}^{L} \hat{\mathbf{a}}_i\hat{\mathbf{b}}_i^H, \tag{53}
\]

where \( \hat{\mathbf{a}}_i \) and \( \hat{\mathbf{b}}_i \), respectively, are the columns of \( \hat{\mathbf{A}} \) and \( \hat{\mathbf{B}} \). Similarly to the SVD case, the recovered GCC is obtained as

\[
\hat{\phi}_{12} = \| \hat{\phi} \|_F \| \mathbb{R} \{ \hat{a}_1 \} \| \text{sign}(\mathbb{R} \{ \hat{a}_1[\gamma] \}), \tag{54}
\]

where \( \mathbb{R} \{ \hat{a}_1[\gamma] \} \) is the element of \( \mathbb{R} \{ \hat{a}_1 \} \) having the maximum absolute value, i.e.

\[
\gamma = \arg \max_n |\mathbb{R} \{ \hat{a}_1[n] \} |. \tag{55}
\]

The target components resulting from the considered speech examples are shown in the last column of Figure 3(a). The recovered GCCs from the weighted SVD (WSVD FS-GCC) are shown in the last column of Figure 3(b).

1) Weighting: Note that the weights \( \omega_l \) can be directly related to the \( a_l \) coefficients of the model in Eq. (26). Weights having a value close to 1 must reflect that the corresponding band provides almost perfect delay information. In contrast, weights close to zero should reflect that the frequency band is dominated by noise and its information should be discarded. Similarly, perfect sub-bands are expected to have a magnitude GCC which is only dependent on the displaced window.
response $\phi_{12}$, as expressed by Eq. (23). Therefore, the average of the magnitude of a perfect sub-band GCC ($\alpha_l = 1$), regardless the true TDOA, will be:

$$|r_l|_{\alpha=1} = \frac{1}{N} \sum_{n=0}^{N-1} |\phi[n]|. \quad (56)$$

In contrast, GCCs from completely noisy sub-bands ($\alpha_l = 0$) are given by noise realizations $n_l$. The magnitude of a noisy band, which follows a Rayleigh distribution, will tend to its mean value:

$$|r_l|_{\alpha=0} = \sqrt{\frac{\pi}{2}} \frac{\|\phi\|^2}{2N}. \quad (57)$$

Taking the above two extreme cases into account, the proposed weights are:

$$w_l = \begin{cases} g_l, & g_l \geq 0 \\ 0, & g_l < 0, \end{cases} \quad (58)$$

where

$$g_l = \frac{|r_l|_{\alpha=0} - \frac{1}{N} \sum_{n=0}^{N-1} |r_l[n]|}{|r_l|_{\alpha=0} - |r_l|_{\alpha=1}}. \quad (59)$$

Therefore, the weights are expected to vary between 1 (perfect sub-bands) and 0 (completely noisy sub-bands).

V. Experiments

This section describes the experiments conducted to show the advantages of the proposed FS-GCC method in terms of TDE performance. The criteria used to assess such performance and the complete experimental set-up are next described.

A. Performance Criteria

We classify a time delay estimate as either an anomaly or a nonanomaly according to its absolute error $e_i = |\tau - \hat{\tau}|$, where $\tau$ is the true time delay and $\hat{\tau}$ is the $i$-th time delay estimate. If $e_i > T_c/2$, the estimate is assumed to be anomalous, where $T_c$ is the signal correlation time [23]. For our particular source signal (speech), $T_c$ was computed as the width of the main lobe of its autocorrelation function (taken between the -3 dB points), which is equal to 24 samples. The TDE performance is evaluated in terms of the percentage of anomalous estimates over the total estimates ($P_\tau$), the GCC peak SNR, the mean absolute error (MAE) and the standard deviation for the subset of nonanomalous estimates ($\rho_{\tau, na}$, $\text{MAE}_{\tau, na}$, $\text{SDAE}_{\tau, na}$). These measures are defined as

$$P_\tau = \frac{N_a}{N_T}, \quad (60)$$

$$\text{MAE}_{\tau, na} = \frac{1}{N_{na}} \sum_{i \in \chi_{na}} e_i, \quad (61)$$

$$\text{SDAE}_{\tau, na} = \sqrt{\frac{1}{N_{na}} \sum_{i \in \chi_{na}} (e_i - \text{MAE}_{\tau, na})^2}, \quad (62)$$

where $N_T$ denotes the total number of estimates, $N_a$ is the number of estimates that are identified as anomalies, $N_{na}$ is the number of nonanomalous estimates, and $\chi_{na}$ represents the subset of nonanomalous estimates. The GCC Peak SNR is defined as the gain of the maximum GCC peak with respect to the average value of the rest of peaks, i.e.

$$\rho_{\tau, na} = 20 \log_{10} \left( \frac{\max(\hat{R}_{12, na}(\tau))}{\frac{1}{|P_K|} \sum_{\tau \in P_K} \hat{R}_{12, na}(\tau)} \right), \quad (63)$$

where $P_K$ is the subset of time lags corresponding to local peaks in a nonanomalous GCC, defined as those GCC samples larger than their two neighboring values, and $|P_K|$ its cardinality.
B. Simulation Set-up and Algorithm Parameters

We consider a rectangular room simulated by the image-source method in a single source scenario [24]. Synthetic impulse responses were generated for a pair of sensors separated 0.5 meters considering 10 random array positions and orientations within the room, as well as 10 random source locations for each microphone configuration. The simulations were repeated for each reverberant condition. The following parameters were used:

- Room dimensions: $6 \times 7 \times 3$ meters ($x \times y \times z$).
- Uniform reflection coefficients: $r_i \in \{0.0, 0.8\}$
- Source positions: 10 random positions on the plane ($x, y, z = 1.25$).
- Microphone positions: two-microphone array with inter-sensor spacing 0.5 m, with 10 random positions and orientations on the $x - y$ plane ($z = 1.25$).
- SNR: Varying between -10 dB and 20 dB. For each array set-up and source position, 50 different noise realizations were generated for each SNR condition. To control the SNR, mutually independent white Gaussian noise was properly scaled and added to each microphone signal.
- Source signal: A male speech signal of 2 seconds duration, digitized with 16-bit resolution at 44.1 kHz. The signal was processed to eliminate non-activity segments. The synthetic microphone signals obtained by convolving the source signal with the generated impulse responses were processed by the different methods in the Short-Time Fourier Transform (STFT) domain. We used a frame length of 2048 samples and Hann windowing with 75% overlap, leading to 177 frames per audio example. The total number of estimates used to evaluate each method at each SNR and reverberant condition is therefore $N_T = 10 \times 10 \times 50 \times 177 = 885,000$.

The parameters used for evaluating the FS-GCC approach were $B = 128$ (spectral window length) and $M = 32$ (hop) frequency bins. Results for a blind channel identification method, Adaptive Eigenvalue Decomposition (AED) [15], are also given for comparison using rectangular windows of the same size (2048). The filter length was set to 512 samples, with an adaptation step of $\mu = 0.003$. Since AED is not a GCC-based method, the GCC peak SNR is not provided for such algorithm.

C. TDE Results

The results for the anechoic condition with a varying SNR are shown in Fig. 6. The percentage of anomalous estimates is clearly reduced for all the methods with respect to the conventional GCC-PHAT, with significant improvements achieved by WSVF FS-GCC and, especially, AED, although both follow a similar behavior. The biggest improvement is observed for SNR = 0 dB, where the difference between WSVF FS-GCC
and conventional GCC is close to 35 percentage points (40 in the case of AED). The GCC Peak SNR is significantly better for the FS-GCC methods than for the conventional GCC, especially at higher SNRs. All the methods outperform as well the conventional GCC in terms of mean and standard deviation of time-delay errors, following a similar behavior. This is an interesting result, since it means that having a lower temporal resolution due to the windowing effect does not affect negatively the TDE accuracy of FS-GCC.

The results for the reverberant case \( r_i = 0.8 \) are shown in Fig. 7. The percentage of anomalous estimates are now worse for all methods, but in this case, AED is the one more significantly affected by reverberation. In contrast, WSVD FS-GCC still shows very good robustness, with the most significant difference (more than 35 percentage points) at SNR = 10 dB. The Peak SNR is again considerably better for both FS-GCC methods, with SVD providing slightly better results than WSVD. Regarding nonanomalous TDOA errors, the FS-GCC methods provide slightly better results at low SNRs. At higher SNRs the conventional GCC seems to be slightly more accurate, although in all cases the differences are very small (below 1 sample).

### D. Impact on Source Localization Performance

Although accurate time delay estimates are assumed to lead to better localization results, the advantages in terms of Peak SNR are also expected to contribute to better localization in SRP-based approaches, due to the mitigation of noise in the GCCs. To support such claim, experiments were conducted considering the same acoustic conditions and source signals but with six distributed microphones placed at the walls and corners of the room. The modified SRP algorithm (M-SRP) \cite{25} was applied considering a grid resolution of 0.15 m. Fig. 8 shows an example of the resulting SRP maps when using conventional GCCs (a) and the proposed WSVD FS-GCCs (b) for the same signal frame (SNR = 0 dB). The improvement in terms of robustness to noise is clearly observed. The results for the mean and median absolute location errors are specified in Tables I and II respectively, for anechoic and reverberant conditions. For comparison purposes, localization performance for AED is also provided by estimating the source location as the point of the grid having the lowest mean squared error considering all the available TDOAs. It can be observed that FS-GCC provides always more accurate location estimates and less anomalous detections (lower median) both in the anechoic case and in the reverberant case. Note that in the very worst case of SNR = -10 dB and reverberation, all the methods provide unreliable location estimates.

### Table I

**LOCALIZATION ERROR [METERS] FOR \( r_i = 0 \)**

| Method   | SNR = 20 dB | SNR = 10 dB | SNR = 0 dB | SNR = -10 dB |
|----------|-------------|-------------|------------|---------------|
| GCC      | Mean | Median | Mean | Median | Mean | Median | Mean | Median |
| 0.2510  | 0.0839 | 0.6786 | 0.0844 | 1.9216 | 1.8230 | 2.7655 | 2.7102 |
| FS-GCC   | 0.0716 | 0.5095 | 0.0819 | 0.0702 | 0.3685 | 0.0839 | 1.5298 | 0.4895 |
| AED      | 0.9542 | 0.0702 | 0.9002 | 0.0702 | 1.3457 | 0.5662 | 1.9669 | 1.7781 |

### Table II

**LOCALIZATION ERROR [METERS] FOR \( r_i = 0.8 \)**

| Method   | SNR = 20 dB | SNR = 10 dB | SNR = 0 dB | SNR = -10 dB |
|----------|-------------|-------------|------------|---------------|
| GCC      | Mean | Median | Mean | Median | Mean | Median | Mean | Median |
| 1.5722  | 0.9079 | 2.4151 | 2.4198 | 2.7016 | 2.6541 | 2.7025 | 2.6055 |
| FS-GCC   | 0.2825 | 0.0839 | 0.6675 | 0.0926 | 1.5737 | 0.9295 | 2.7053 | 2.5615 |
| AED      | 1.8427 | 1.6497 | 1.8589 | 1.8054 | 2.6129 | 2.5434 |

### VI. Conclusion

This paper presented an improved GCC-based technique for TDE based on a sub-band analysis of the cross-power spectrum phase. The properties resulting from the so-called frequency-sliding GCC (FS-GCC) allows the recovering of denoised correlation signals by means of low-rank approximations of the FS-GCC matrix. The use of SVD and weighted SVD for obtaining both robust GCCs and accurate time delay estimates has been validated and compared to other well-known approaches, showing the relevant impact that the proposed technique can have in TDE and source localization performance.
