Abstract
This paper is triggered by the preprint “Computing Matrix Squareroot via Non Convex Local Search” by Jain et al. (arXiv:1507.05854), which analyzes gradient-descent for computing the square root of a positive definite matrix. Contrary to claims of Jain et al. [14], our experiments reveal that Newton-like methods compute matrix square roots rapidly and reliably, even for highly ill-conditioned matrices and without requiring commutativity. We observe that gradient-descent converges very slowly primarily due to tiny step-sizes and ill-conditioning. We derive an alternative first-order method based on geodesic convexity: our method admits a transparent convergence analysis (< 1 page), attains linear rate, and displays reliable convergence even for rank deficient problems. Though superior to gradient-descent, ultimately our method is also outperformed by a well-known scaled Newton method. Nevertheless, the primary value of our work is its conceptual value: it shows that for deriving gradient based methods for the matrix square root, the manifold geometric view of positive definite matrices can be much more advantageous than the Euclidean view.

1 Introduction
Matrix functions such as $A^\alpha$, $\log A$, or $e^A$ ($A \in \mathbb{C}^{n \times n}$) arise in diverse contexts. Higham [9] provides an engaging overview on the topic of matrix functions. A building block for efficient numerical evaluation of various matrix functions is the matrix square root $A^{1/2}$, a function whose computation has witnessed great interest in the literature [1, 2, 8, 10, 12, 20]; see also [9, Ch. 6].

The present paper revisits the problem of computing the matrix square root for a symmetric positive semidefinite (psd) matrix. Our work is triggered by the recent note of [14], who analyze a simple gradient-descent procedure for computing $A^{1/2}$ for a given psd matrix $A$. Jain et al. [14] motivate their work by citing weaknesses of a direct application of Newton’s method (Algorithm X in [10]), which is known to suffer from ill-conditioning and whose convergence analysis depends on commutativity of its iterates, and thus breaks down as round-off error invalidates commutativity.

However, it turns out that the modified “polar-Newton” (PN) method of [9, Alg. 6.21] avoids these drawbacks, and offers a theoretically sound method with excellent practical behavior. At the same time, gradient-descent of [14], while initially appealing due to its simplicity, turns out to be empirically weak: it converges extremely slowly, especially on ill-conditioned matrices because its stepsizes become too small to ensure progress on computers with limited floating point computation.

At the expense of introducing “yet another matrix square root” (YAMSR) method, we present a non-Euclidean first-order method grounded in the geometric optimization framework of [23]. Our method admits a transparent convergence analysis, attains linear (geometric) convergence rate, and displays reliable behavior even for highly ill-conditioned problems (including rank-deficient problems). Although numerically superior to the gradient-descent approach of [14], like other linearly convergent strategies YAMS is still outperformed by the well-known polar-Newton (scaled Newton) method.

In light of these observations, there are two key messages delivered by our paper:

---

1 The same ideas extend trivially to the Hermitian psd case.
None of the currently known (to us) first-order methods are competitive with the established second-order polar-Newton algorithm for computing matrix square roots.

The actual value of this paper is conceptual: it shows that for deriving gradient based methods that compute matrix square roots, the differential geometric view of positive definite matrices is much more advantageous than the Euclidean view.

As a further attestation to the latter claim, we note that our analysis yields as a byproduct a convergence proof of a (Euclidean) iteration due to Ando [2], which previously required a more intricate analysis. Moreover, we also obtain a geometric rate of convergence.

Finally, we note that the above conceptual view underlies several other applications too, where the geometric view of positive definite matrices has also proved quite useful, e.g., [7, 11, 22–26].

1.1 Summary of existing methods

To place our statements in wider perspective we cite below several methods for matrix square roots. We refer the reader to [9, Chapters 6, 8] for more details and many more references, as well as a broader historical perspective. For a condensed summary, we refer the reader to the survey of Iannazzo [12] which covers the slightly more general problem of computing the matrix geometric mean.

1. Eigenvectors: Compute the decomposition $A = UΛU^*$ and obtain $A^{1/2} = UΛ^{1/2}U^*$. While tempting, this can be slower for large and ill-conditioned matrices. In our case, since $A > 0$, this method coincides with the Schur-Cholesky method mentioned in [12].

2. Matrix averaging: Many methods exist that obtain the matrix geometric mean as a limit of simpler averaging procedures. These include scaled averaging iterations (which is essentially a matrix Harmonic-Arithmetic mean iteration that converges to the geometric mean) and their variants [12, §5.1]. In spirit, the algorithm that we propose in this paper also falls in this category.

3. Newton-like: The classic Newton iteration of [10], whose weaknesses motivate the gradient-descent procedure of [14]. However, a better way to implement this iteration is to use polar decomposition. Here, first we compute the Cholesky factorization $A = R^TR$, then obtain the square root as $A^{1/2} = UR$, where $U$ is the unitary polar factor of $R^{-1}$. This polar factor could be computed using the SVD of $R$, but the polar-Newton (PN) iteration [9, Alg. 6.21] avoids that and instead uses the scaled Newton method

$$U_{k+1} = \frac{1}{2} \left( μ_kU_k + μ_k^{-1}U_k^{-T} \right), \quad U_0 = R.$$  

This iteration has the benefit that the number of steps needed to attain a desired tolerance can be predicted in advance, and it can be implemented to be backward stable. It turns out that empirically this iteration is works reliably even for extremely ill-conditioned matrices, and converges (locally) superlinearly. The scaled Halley-iteration of Nakatsukasa et al. [20] converges even more rapidly and can be implemented in a numerically stable manner [19].

4. Quadrature: Methods based on Gaussian and Gauss-Chebyshev quadrature and rational minimax approximations to $z^{-1/2}$ are surveyed in [12, §5.4]. Among others, these methods easily tackle computation of general powers, logarithms, and some other matrix functions [8, 13].

5. First-order methods: The binomial iteration which uses $(I - C)^{1/2} = I - \sum_j α_jC^j$ for suitable $α_j > 0$ and applies when $ρ(C) < 1$ [9, §6.8.1]. The gradient-descent method of [14] which minimizes $‖X^2 - A‖^2_F$. Like the binomial iteration, this method does not depend on linear system solves (or matrix inversions) and uses only matrix multiplication. The method introduced in section 2.1 is also a first-order method, though cast in a non-Euclidean space; it does, however, require (Cholesky based) linear system solves.

Presumably, the same conclusion also holds for many other matrix functions such as powers and logarithms.
We mention other related work in passing: fast computation of a matrix $C$ such that $A^p \approx CC^T$ for SDD matrices [6]; Krylov-subspace methods and randomized algorithms for computing the product $f(A)b$ [9, Chapter 13]; and the broader topic of multivariate matrix means [3, 5, 15, 17, 21, 22].

2 Geometric Optimization

We present details of computing the matrix square root using geometric optimization. Specifically, we cast the problem of computing matrix square roots into the nonconvex optimization problem

$$
\min_{X > 0} \, \delta_2(X, A) + \delta_2(X, I),
$$

(2.1)

whose unique solution is the desired matrix square root $X^* = A^{1/2}$; here $\delta_2$ denotes the S-Divergence [22]:

$$
\delta_2(X, Y) := \log \det \left( \frac{X+Y}{2} \right) - \frac{1}{2} \log \det(XY).
$$

(2.2)

To present our algorithm for solving (2.1) let us first recall some background.

The crucial property that helps us solve (2.1) is geodesic convexity of $\delta_2$, that is, convexity along geodesics in $\mathbb{P}^n$. Consider thus, the geodesic (see [4, Ch. 6] for a proof that this is the geodesic):

$$
X^t Y := X^{1/2}(X^{-1/2} Y X^{-1/2})^t X^{1/2}, \quad X, Y > 0, \quad t \in [0, 1],
$$

(2.3)

that joins $X$ to $Y$. A function $f : \mathbb{P}^n \to \mathbb{R}$ is called geodesically convex (g-convex) if it satisfies

$$
f(X^t Y) \leq (1-t)f(X) + tf(Y).
$$

(2.4)

Theorem 1. The S-Divergence (2.2) is jointly geodesically convex on (Hermitian) psd matrices.

Proof. See [22, Theorem 4.4]; we include a proof in the appendix for the reader’s convenience. 

Similar to Euclidean convexity, g-convexity bestows the crucial property: “local $\implies$ global.” Consequently, we may use any algorithm that ensures local optimality; g-convexity will imply global optimality. We present one such algorithm in section 2.1 below.

But first let us see why solving (2.1) yields the desired matrix square root.

Theorem 2. Let $A, B > 0$. Then,

$$
A^{\#}_{1/2}B = \arg\min_{X > 0} \, \delta_2(X, A) + \delta_2(X, B).
$$

(2.5)

Moreover, $A^{\#}_{1/2}B$ is equidistant from $A$ and $B$, i.e., $\delta_2(A, A^{\#}_{1/2}B) = \delta_2(B, A^{\#}_{1/2}B)$.

Proof. See [22, Theorem 4.1]. We include a proof below for convenience.

Since the constraint set is open, we can simply differentiate the objective in (2.5), and set the derivative to zero to obtain the necessary condition

$$
\left( \frac{X+A}{2} \right)^{-1} + \left( \frac{X+B}{2} \right)^{-1} X^{-1} = 0,
$$

$$
\implies \quad X^{-1} = (X+A)^{-1} + (X+B)^{-1}
$$

$$
\implies \quad (X+A)X^{-1}(X+B) = 2X + A + B
$$

$$
\implies \quad B =XA^{-1}X.
$$

The latter is a Riccati equation whose unique positive solution is $X = A^{\#}_{1/2}B$—see [4, Prop 1.2.13].

Global optimality of this solution follows easily since $\delta_2$ is g-convex as per Thm. 1.

Corollary 3. The unique solution to (2.1) is $X^* = A^{\#}_{1/2}I = A^{1/2}$.

\footnote{There is a typo in the cited result, in that it uses $A$ and $A^{1/2}$ where it should use $A^{-1}$ and $A^{-1/2}$.}
2.1 Algorithm for matrix square root

We present now an iteration for solving $(2.1)$. As for Thm. 2, we obtain here the optimality condition

$$X^{-1} = (X + A)^{-1} + (X + I)^{-1}.$$  

(2.6)

Our algorithm solves (2.6) simply by running⁴

\[
\begin{align*}
X_0 &= \frac{1}{2}(A + I) \tag{2.7} \\
X_{k+1} &\leftarrow [(X_k + A)^{-1} + (X_k + I)^{-1}]^{-1}, \quad k = 0, 1, \ldots \tag{2.8}
\end{align*}
\]

The following facts about our algorithm and its analysis are noteworthy:

1. Towards completion of this article we discovered that iteration (2.8) has been known in matrix analysis since over three decades! Indeed, motivated by electrical resistance networks, Ando [2] analyzed exactly the same iteration as (2.8) in 1981. Our convergence proof (Theorem 4) is much shorter and more transparent—it not only reveals the geometry behind its convergence but also yields explicit bounds on the convergence rate, thus offering a new understanding of the classical work of Ando [2].

2. Initialization (2.7) is just one of many. Any matrix in the psd interval $[2(I + A)^{-1}, \frac{1}{2}(A + I)]$ is equally valid; different choices can lead to better empirical convergence.

3. Each iteration of the algorithm involves three matrix inverses. Theoretically, this costs “just” $O(n^2)$ operations. In practice, we compute (2.8) using linear system solves; in MATLAB notation:

\[
R = (X+A)\backslash I + (X+I)\backslash I; \quad X = R\backslash I;
\]

4. The gradient-descent method of [14] and the binomial method [9] do not require solving linear systems, and rely purely on matrix multiplication. But both turn out to be slower than (2.8) while also being more sensitive to ill-conditioning.

5. For ill-conditioned matrices, it is better to iterate (2.8) with $aI$, for a suitable scalar $a > 0$; the final solution is recovered by dowscaling by $a^{-1/2}$. A heuristic choice is $a = \text{tr}(A)/\sqrt{n}$, which seems to work well in practice (for well-conditioned matrices $a = 1$ is preferable).

Theorem 4 (Convergence). Let $\{X_k\}_{k \geq 0}$ be generated by (2.7)-(2.8). Let $X^* = A^{1/2}$ be the optimal solution to (2.1). Then, there exists a constant $\gamma < 1$ such that $\delta_k^2(X_k, X^*) \leq \gamma^k \delta_0^2(X_0, X^*)$. Moreover, $\lim X_k = X^*$.

Proof. Our proof is a specialization of the fixed-point theory in [18, 23]. Specifically, we prove that (2.8) is a fixed-point iteration under the Thompson part metric

$$\delta_T(X, Y) := \| \log(X^{-1/2}YX^{-1/2})\|,$$  

(2.9)

where $\| \cdot \|$ is the usual operator norm. The metric (2.9) satisfies many remarkable properties; for our purpose, we need the following three well-known properties (see e.g., [23, Prop. 4.2]):

\[
\begin{align*}
\delta_T(X^{-1}, Y^{-1}) &= \delta_T(X, Y), & \delta_T(X + A, Y + B) &\leq \max\{\delta_T(X, Y), \delta_T(A, B)\}, \\
\delta_T(X + A, Y + A) &\leq \frac{a}{\lambda_{\min}(A)} \delta_T(X, Y), & \alpha &= \max\{\|X\|, \|Y\|\}.
\end{align*}
\]

(2.10)

Consider now the nonlinear map

$$G \equiv X \mapsto [(X + A)^{-1} + (X + I)^{-1}]^{-1},$$

⁴Observe that the same algorithm also computes $A^nI^{1/2}$ if we replace $I$ by $B$ in (2.7) and (2.8).
corresponding to iteration (2.8). Using properties (2.10) of the Thompson metric $\delta_T$ we have

$$
\delta_T(\mathcal{G}(X), \mathcal{G}(Y)) = \delta_T([(X + A)^{-1} + (X + I)^{-1}]^{-1}, [(Y + A)^{-1} + (Y + I)^{-1}]^{-1})
\leq \max \{\delta_T((X + A)^{-1}, (Y + A)^{-1}), \delta_T((X + I)^{-1}, (Y + I)^{-1})\}
\leq \gamma_1 \delta_T(X, Y), \quad \gamma_1 = \frac{\delta}{\alpha + \lambda_{\min}(A)} \cdot \gamma_2 = \frac{\delta}{\alpha + 1}, \quad \alpha = \max \{\|X\|, \|Y\|\},
$$

where we can choose $\gamma$ to be independent of $X$ and $Y$. Thus, the map $\mathcal{G}$ is a strict contraction. Hence, from the Banach contraction theorem it follows that $\delta_T(X_k, X^*)$ converges at a linear rate given by $\gamma$, and that $X_k \to X^*$. Notice that $\mathcal{G}$ maps the (compact) interval $[2(I + A^{-1})^{-1}, \frac{1}{2}(A + I)]$ to itself. Thus, $\alpha \leq \frac{1}{2} \|I + A\|$; since $\frac{\delta}{\alpha + \alpha}$ is increasing, we can easily upper-bound $\gamma_1, \gamma_2$ to finally obtain

$$
\gamma = \frac{1 + \|A\|}{1 + \|A\| + 2 \min(\lambda_{\min}(A), 1)}.
$$

This is strictly smaller than 1 if $A > 0$, thus yielding an explicit contraction rate.

**Remark 1:** The bound on $\gamma$ above is a worst-case bound. Empirically, the value of $\alpha$ in the bound is usually much smaller and the convergence rate commensurately faster.

**Remark 2:** Starting with $X_0 = \frac{1}{2}(A + I)$ ensures that $X_0 > 0$; thus, we can use the iteration (2.8) even if $A$ is semidefinite, as all intermediate iterates remain well-defined. This suggests why iteration (2.8) is empirically robust against ill-conditioning.

**Example 1.** Suppose $A = 0$. Then, the map $\mathcal{G}$ is no longer contractive but still nonexpansive. Iterating (2.8) generates the sequence $\{X_k\} = \{\frac{1}{2}I, \frac{3}{8}I, \frac{33}{112}I, \ldots\}$, which converges to zero.

Example 1 shows that iteration (2.8) remains well-defined even for the zero matrix. This prompts us to take a closer look at computing square roots of low-rank semidefinite matrices. In particular, we extend the definition of the $S$-Divergence to low-rank matrices. Let $A$ be a rank-$r$ semidefinite matrix of size $n \times n$ where $r \leq n$. Then, define $\det_r(A) := \prod_{i=1}^r \lambda_i(A)$ to be product of its $r$ positive eigenvalues. Using this, we can extend (2.2) as

$$
\delta^2_S(X, Y) := \log \det_r \left( \frac{X + Y}{2} \right) - \frac{1}{2} \log \det_r(X) - \frac{1}{2} \log \det_r(Y),
$$

for rank-$r$ SPD matrices $X$ and $Y$. If $\text{rank}(X) \neq \text{rank}(Y)$, we set $\delta^2_S(X, Y) = +\infty$. The above definition can also be obtained as a limiting form of (2.2) by applying $\delta^2_S$ to rank deficient $X$ and $Y$ by considering $X + \epsilon I$ and $Y + \epsilon I$ and letting $\epsilon \to 0$.

Although iteration (2.8) works remarkably well in practice, it is a question of future interest on how to obtain square roots for rank deficient matrices faster by exploiting (2.11) instead.

### 3 Numerical results

We present numerical results comparing running times and accuracy attained by: (i) YAMS; (ii) GD; (iii) LS; and (iv) PN. These methods respectively refer to iteration (2.8), the fixed step-size gradient-descent procedure of [14], our line-search based implementation of gradient-descent, and the polar-Newton iteration of [9, Alg. 6.21].

We present only one experiment with GD, because with fixed steps it vastly underperforms all other methods. In particular, if we set the step size according to the theoretical bounds of [14], then
for matrices with large condition numbers the step size becomes smaller than machine precision! In our experiments with GD we used step sizes much larger than theoretical ones, otherwise the method makes practically no progress at all. More realistically, if we wish to use gradient-descent we must employ line-search. Ultimately, although substantially superior to plain GD, even LSGD turns out to be outperformed by YAMSR, which in turn is superseded by PN.

We experiment with the following matrices:

1. $I + \beta U U^T$ for a low-rank matrix $U$ and a variable constant $\beta$. These matrices are well-conditioned.
2. Random Correlation matrices (MATLAB: gallery(’randcorr’, n)); medium conditioned.
3. The Hilbert matrix (MATLAB: hilb(n)). This is a well-known ill-conditioned matrix class.
4. The inverse Hilbert matrix (MATLAB: invhilb(n)). The entries of the inverse Hilbert matrix are very large integers. Extremely ill-conditioned.

Figure 1: Running time comparison between GD and LSGD; this behavior is typical.

Figure 2: Running time comparison: YAMSR vs LSGD; this behavior is typical ($\kappa$ is condition number).

Figure 3: Running time comparison between YAMSR and PN; this behavior is also typical.
Figure 4: Square root computation of a $500 \times 500$ low-rank (rank 50) covariance matrix.

4 Conclusions

We revisited computation of the matrix square root, and compared the recent gradient-descent procedure of [14] against the standard polar-Newton method of [9, Alg. 6.21], as well as YAMSR, a new first-order fixed-point algorithm that we derived using the viewpoint of geometric optimization. The experimental results show that the polar-Newton method is the clear winner for computing matrix square roots (except near the $10^{-15}$ accuracy level for well-conditioned matrices). Among the first-order methods YAMSR outperforms both gradient-descent as well its superior line-search variant across all tested settings, including singular matrices.

A Technical details

Proof of Theorem 1. It suffices to prove midpoint convexity; the general case follows by continuity. Consider therefore psd matrices $X_1, X_2, Y_1, Y_2$. We need to show that

$$\delta^2_2(X_1 \#_{1/2} X_2, Y_1 \#_{1/2} Y_2) \leq \frac{1}{2} \delta^2_2(X_1, Y_1) + \frac{1}{2} \delta^2_2(X_2, Y_2). \tag{A.1}$$

From the joint concavity of the operator $\#_{1/2}$ [16] we know that

$$X_1 \#_{1/2} X_1 + Y_1 \#_{1/2} Y_2 \preceq (X_1 + Y_1) \#_{1/2} (X_2 + Y_2).$$

Since log det is a monotonic function, applying it to this inequality yields

$$\log \det[(X_1 + Y_1) \#_{1/2} (X_2 + Y_2)] \leq \log \det[(X_1 \#_{1/2} X_2) + (Y_1 \#_{1/2} Y_2)]. \tag{A.2}$$

But we also know that $\log \det((1-t)X + tY) = (1-t) \log \det(X) + t \log \det(Y)$. Thus, a brief algebraic manipulation of (A.2) combined with the definition (2.2) yields inequality (A.1) as desired. \qed
