Abstract

We make use of sensitive (9.3 $\mu$Jy beam$^{-1}$ rms) 1.2 mm continuum observations from the Atacama Large Millimeter/submillimeter Array (ALMA) Spectroscopic Survey in the Hubble Ultra-Deep Field (ASPECS) large program to probe dust-enshrouded star formation from 1362 Lyman-break galaxies spanning the redshift range $z = 1.5–10$ to $\sim$2–28 $M_\odot$ yr$^{-1}$ at 4$\sigma$ over the entire range. We find that the fraction of ALMA-detected galaxies in our $z = 1.5–10$ samples increases steeply with stellar mass, with the detection fraction rising from 0% at $10^{9.0}$ $M_\odot$ to 85$^{+18}_{-19}$% at $>10^{10}$ $M_\odot$. Moreover, on stacking all 1253 low-mass (<$10^{9.25}$ $M_\odot$) galaxies over the ASPECS footprint, we find a mean continuum flux of $-0.1 \pm 0.4$ $\mu$Jy beam$^{-1}$, implying a hard upper limit on the obscured star formation rate of <0.6 $M_\odot$ yr$^{-1}$ (4$\sigma$) in a typical low-mass galaxy. The correlation between the infrared excess (IRX) of UV-selected galaxies ($L_{IR}/L_{UV}$) and the UV-continuum slope is also seen in our ASPECS data and shows consistency with a Calzetti-like relation at $>10^{9.5}$ $M_\odot$ and an SMC-like relation at lower masses. Using stellar mass and $\beta$ measurements for $z \sim 2$ galaxies over the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey, we derive a new empirical relation between $\beta$ and stellar mass and then use this correlation to show that our IRX–$\beta$ and IRX–stellar mass relations are consistent with each other. We then use these constraints to express the IRX as a bivariate function of $\beta$ and stellar mass. Finally, we present updated estimates of star formation rate density determinations at $z > 3$, leveraging present improvements in the measured IRX and recent probes of ultraluminous far-IR galaxies at $z > 2$.

Unified Astronomy Thesisaurus concepts: Lyman-break galaxies (979); Infrared excess (788); High-redshift galaxies (734); Dust continuum emission (412); Far infrared astronomy (529)

1. Introduction

One significant focal point in studies of galaxy formation and evolution has been a careful quantification of the cosmic star formation history. Knowing when most of the stars were formed across cosmic time is important for understanding the build-up of metals, for interpreting the stellar populations in both dwarf galaxies and stellar streams in the halo of our Galaxy, and for interpreting cosmic reionization. At the present, there is a rough consensus that the overall cosmic star formation increases from early times to $z \sim 3$, reaching an approximate peak at a redshift of $z \sim 2–3$, 2 billion years after the Big Bang, and then finally decreases at $z < 1$ (Madau & Dickinson 2014).

Because of the different observational techniques required, determinations of the cosmic star formation rate (SFR) density have typically been divided between that fraction of star formation activity directly observable from rest-UV light and that obscured by dust which can be inferred from the far-IR

21 Humboldt Research Fellow.
emission from galaxies. Determinations of the unobscured rest-UV SFR density has shown generally good agreement overall in terms of different results in the literature (e.g., Madau & Dickinson 2014; Stark 2016) thanks to the relatively straightforward procedures for selecting such sources (e.g., Steidel et al. 1996) and substantial sensitive near-IR probes to 1.6 μm allowing for an efficient probe of such star formation to \( z \sim 2 \) (e.g., Oesch et al. 2018). Determinations of the obscured SFR density out to \( z \sim 3 \) are also more mature thanks to the significant numbers of long-wavelength Spitzer and Herschel observations acquired over a wide variety of legacy fields (Reddy et al. 2008; Daddi et al. 2009; Magnelli et al. 2009, 2011, 2013; Karim et al. 2011; Cucciati et al. 2012; Álvarez-Márquez et al. 2016).

In samples of star-forming galaxies with both obscured and unobscured SFR estimates, there has been great interest in determining the ratio of the two quantities, which has traditionally been expressed in terms of the ratio of the IR luminosity \( L_{\text{IR}} \) and UV luminosity \( L_{\text{UV}} \) of a galaxy. This quantity is known as the infrared excess (IRX; where \( \text{IRX} = L_{\text{IR}}/ L_{\text{UV}} \)), and the correlation of IRX with the UV-continuum slope \( \beta \) (or stellar mass) conveniently allows for an estimate of the IR luminosity or obscured SFR of galaxies where no far-IR observations are available.

In spite of the significant utility of Herschel and Spitzer/ MIPS (Multiband Imaging Photometer) for probing obscured star formation out to \( z \sim 3 \), it has been much more challenging to use these same facilities to probe such star formation at \( z > 3 \). The availability of high-resolution Atacama Large Millimeter/submillimeter Array (ALMA) observations over extragalactic legacy fields has significantly revolutionized our attempt to probe obscured star formation in this regime, both in normal star-forming galaxies and also in more extreme star-forming galaxies which are almost entirely obscured at rest-UV wavelengths (e.g., Hodge et al. 2013; Stach et al. 2019). The targeted observations of modest samples of bright star-forming galaxies at \( z \sim 5-8 \) have been particularly impactful (Capak et al. 2015; Bowler et al. 2018; Hashimoto et al. 2018; Harikane et al. 2020; Béthermin et al. 2020; S. Schouwss et al. 2020, in preparation) and deep studies of star-forming galaxies in the Hubble Ultra-Deep Field (Aravena et al. 2016; Bouwens et al. 2016; Dunlop et al. 2017; Mcleure et al. 2018).

While there are clearly some \( z > 3 \) sources which are well detected in the far-IR continuum with ALMA (Watson et al. 2015; Knudsen et al. 2017; Hashimoto et al. 2019), the vast majority of UV-selected \( z > 3 \) sources are not detected individually in the available ALMA continuum observations, suggesting that only a fraction of the star formation activity at \( z > 3 \) is obscured by dust. However, this interpretation depends significantly on the assumed spectral energy distribution (SED) shape of galaxies in the far-IR, which are needed to infer the total infrared luminosity from single-band ALMA measurements. Specifically, a hotter dust temperature would also make galaxies fainter in band 6 and 7 (1 mm and 870 μm, respectively) observations available for most \( z > 4 \) galaxies (e.g., Bouwens et al. 2016; Barisic et al. 2017; Faist et al. 2017; Baks et al. 2020; but see, however, Simpson et al. 2017; Casey et al. 2018; Dudzevičiūtė et al. 2020). As a result of this, there are a number of ongoing efforts to determine how the dust temperature of star-forming galaxies evolves with cosmic time (Symeonidis et al. 2013; Magnelli et al. 2014; Faist et al. 2017; Knudsen et al. 2017; Dudzevičiūtė et al. 2020).

Meanwhile, ALMA has been instrumental in identifying modest numbers of far-IR bright but UV-faint galaxies in the \( z > 3 \) universe (e.g., Simpson et al. 2014; Franco et al. 2018; Williams et al. 2019; Casey et al. 2019; Wang et al. 2019; Yamaguchi et al. 2019; Dudzevičiūtė et al. 2020). The contributed SFR density of these galaxies to the total SFR density varies from study to study, but in some cases appears to be comparable to the total SFR density of Lyman-break galaxies at \( z \sim 5 \) (Casey et al. 2019; Wang et al. 2019; Dudzevičiūtė et al. 2020). Given the faintness and rarity of these galaxies in the rest-UV, they need to be identified from far-IR detections and their redshifts determined through constraints on the far-IR SED shape or line scans.

Despite progress with ALMA, current constraints on dust obscuration in galaxies at \( z > 3 \) is limited, especially for galaxies at low stellar masses (\(<10^{9.5} M_\odot \)). For these lower-mass galaxies, there has been some debate on whether these galaxies show a steeper SMC-like extinction curve (see, e.g., Reddy et al. 2006; Bouwens et al. 2016; Reddy et al. 2018) or instead exhibit a shallower Calzetti-like form (e.g., McLure et al. 2018).

Fortunately, new sensitive dust-continuum observations have been acquired over a contiguous 4.2 arcmin² region with the Hubble Ultra-Deep Field (HUDF) thanks to the 150 hr ALMA Spectroscopic Survey in the HUDF (ASPECS) large program, obtaining 60 hr of band 3 observations and 90 hr of band 6 observations over the field (González-López et al. 2020). The region chosen for targeting by ASPECS is that region of the HUDF containing the deepest near-IR, optical, X-ray, and radio observations available anywhere in the sky (Beckwith et al. 2006; Bouwens et al. 2011; Ellis et al. 2013; Illingworth et al. 2013; Teplitz et al. 2013; Rujopakarn et al. 2016). These deep, multiband photometric observations have made it possible to identify 1362 UV-selected star-forming galaxies at \( z \sim 1.5-10 \) and to systematically quantify their obscured SFRs as a function of a wide variety of physical properties. The new 1 mm continuum ASPECS observations are sufficiently sensitive to probe dust-obscured SFRs of \( \sim 7-28 M_\odot \text{yr}^{-1} \) at 4z over a \( \sim 5 \times 10^4 M_\odot \text{pc}^3 \) comoving volume in the distant universe. The 4.2 arcmin² targeted with our large program is \( \sim 4 \times \) wider than in our ASPECS pilot program (Aravena et al. 2016; Bouwens et al. 2016; Walter et al. 2016).

The purpose of this paper is to leverage these new observations from the ASPECS program to probe dust-obscured SFRs from 1362 star-forming galaxies at \( z = 1.5-10 \) found over this 4.2 arcmin² ASPECS footprint. The significantly deeper observations not only make it possible for us to conduct a sensitive search for dust-obscured star formation in individual \( z > 3 \) galaxies, but also allow us to reassess the dependence of the IRX on quantities like the UV slope \( \beta \) and stellar mass, while looking at how the dust-obscured SFRs vary from source to source for a given set of physical properties. Thanks to the sensitivity and area of the ASPECS observations, we can derive particularly tight constraints on the obscured star formation from galaxies at lower (\(<10^{9.5} M_\odot \)) stellar masses. Probing to such low stellar masses has been difficult with telescopes like Herschel (e.g., Pannella et al. 2015) due to challenges with source confusion.

In making use of even more sensitive ALMA observations over wider areas to revisit our analyses of the IRX from our pilot program (Bouwens et al. 2016), we can leverage a number of advances. For example, new measurements of the dust
temperature at $z > 3$ from Pavesi et al. (2016), Strandet et al. (2016), Knudsen et al. (2017), Schreiber et al. (2018), and Hashimoto et al. (2019) plausibly allow us to set better constraints on the dust temperature evolution to $z \sim 5$ and beyond. In addition, improved constraints on the obscured SFR density now exist from far-IR bright but UV-faint galaxies based on a variety of wide-area probes (e.g., Simpson et al. 2014; Franco et al. 2018, 2020a; Casey et al. 2019; Wang et al. 2019; Yamaguchi et al. 2019; Dudzevičiūtė et al. 2020). Given these improvements and our more sensitive ALMA observations over the HUDF, a significant aim of the present study will be to obtain improved constraints on the total SFR density of the universe.

Here we provide an outline for our paper. Section 2 provides a brief summary of the ALMA observations we utilize in our analysis, $z = 1.5-10$ galaxy samples, derived stellar masses and UV-continuum slopes, and a fiducial scenario for dust temperature evolution. Section 3 presents the small sample of $z = 1.5-10$ galaxies where we find dust-continuum detections in our ASPECS observations as well as our stack results on the IRX. In Section 4, we look at the implications of our results for dust-obscured SFR and cosmic SFR density at $z \gtrsim 2$. Section 5 provides a summary of the new results obtained from our ASPECS large program.

We refer to the Hubble Space Telescope (HST) F225W, F275W, F336W, F435W, F606W, F775W, F814W, F850LP, F105W, F125W, F140W, and F160W bands as UV225, UV275, $U_{330}$, $B_{435}$, $V_{606}$, $i_{775}$, $I_{814}$, $z_{850}$, $Y_{105}$, $J_{125}$, $H_{140}$, and $K_{160}$, respectively, for simplicity. For consistency with previous work, we find it convenient to quote results in terms of the luminosity $L_\nu$ Steidel et al. (1999) derived at $z \sim 3$, i.e., $M_{1000,AB} = -21.07$. Throughout the paper we assume a standard "concordance" cosmology with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_m = 0.3$ and $\Omega_{\Lambda} = 0.7$, which are in agreement with recent cosmological constraints (Planck Collaboration et al. 2016). Stellar masses and obscured SFRs are quoted assuming a Chabrier (2003) initial mass function (IMF). Magnitudes are in the AB system (Oke & Gunn 1983).

2. Observations and Sample

2.1. ASPECS Band 6, HST, and Spitzer Data

The principal data used are the band 6 ALMA observations from the 2016.1.00324.L program over the HUDF. Those observations were obtained through a full frequency scan in band 6 (212-272 GHz) with ALMA in its most compact configuration. The observations are distributed over 85 pointings separated by 11″ and cover an approximate area of $\sim 4.2$ arcmin$^2$ to near uniform depth. Our construction of a field of wide-area probes (2016.1.00324.L program over the HUDF. Those pointings are $\sim 0.2$ mag deeper than original Beckwith et al. (2006) reductions at optical wavelengths and also provide coverage in the F814W band. The WFC3/IR data available as part of the XDF release include all data from the original HUDF09 (Bouwens et al. 2011), the Cosmic Assembly Near-infrared Deep Extragalactic Legacy Survey (CANDELS; Grogin et al. 2011; Koekemoer et al. 2011), and the HUDF12 (Ellis et al. 2013) programs. Subsequent to the XDF release, only 17 additional orbits of HST imaging data have been obtained with HST over the XDF region (five of which are in the F105W band and 12 in the F435W band). Given that this is <4% of the integration time already included in the XDF release, we elected to use the XDF release due to the effort putting into using super sky flats to optimize the sensitivity.22

For the 0.2-0.4 μm WFC3/UVIS data over the ASPECS field, we made use of the v2 release of the UVUDF epoch 3 data (Teplitz et al. 2013; Rafelski et al. 2015) which included imaging data in the F225W, F275W, and F336W bands. The Spitzer/Infrared Array Camera (IRAC) observations we utilize are from the ~200 hr stacks of the IRAC observations over the HUDF from the GOODS Reionization Era wide-Area Treasury from Spitzer (GREATS) program (M. Stefanon et al. 2020, in preparation; PI: Labbé).

2.2. Flux Measurements

Photometry for sources in our samples is performed in the same way as in the Bouwens et al. (2016) analysis from the ASPECS pilot program. HST fluxes are derived using our own modified version of the SExtractor (Bertin & Arnouts 1996) software. Source detection is performed on the square root of $\chi^2$ image (Szalay et al. 1999; similar to a coadded image) constructed from the $V_{606}$, $i_{775}$, $Y_{105}$, $J_{125}$, $H_{140}$, and $K_{160}$ images. After point-spread function (PSF)-correcting fluxes to match the $H_{160}$-band image, color measurements are made in Kron-style (1980) scalable apertures with a Kron factor of 1.6. “Total magnitude” fluxes are derived by (1) correcting up the fluxes in smaller scalable apertures to account for the additional flux seen in a larger scalable aperture (Kron factor of 2.5) seen on the square root of $\chi^2$ image and (2) correcting for the flux outside these larger scalable apertures and on the wings of the PSF using tabulations of the encircled energy, appropriate for point sources (Dressel 2012).

As in our earlier analysis and many other analyses (e.g., Shapley et al. 2005; Grazian et al. 2006; Labbé et al. 2006, 2010, 2015; Laider et al. 2007; Merlin et al. 2015), Spitzer/IRAC photometry was performed using the HST observations as a template to model the fluxes of sources in the Spitzer/IRAC observations and thus perform photometry below the nominal confusion limit. In performing photometry, a simultaneous fit of the flux of a source of interest and its neighbors is performed, the flux from neighboring sources is subtracted, and then aperture photometry on the source of interest is performed. Photometry is performed in 1.8 diameter circular apertures for the Spitzer/IRAC 3.6 μm and 4.5 μm bands and 2.0 diameter circular apertures for the 5.8 μm and 8.0 μm bands. The observed fluxes are corrected to total based on the inferred growth curve for sources after PSF correction to the Spitzer/IRAC PSF.

A similar procedure is used to derive fluxes for sources from the deep ground-based K-band observations available from the Very Large Telescope (VLT)/Hawk-I UDS and GOODS Survey (Fontana et al. 2014), VLT/ISAAC, and Panoramic Near Infrared Camera (PANIC) observations over the HUDF (5σ depths of 26.5 mag).

---

22 We do nevertheless note the existence of a new Hubble Legacy Field data release (Illingworth et al. 2016; Whitaker et al. 2019), which does include five additional orbits of F105W observations from the Faint Image Grism Survey (FIGS; Pirzkal et al. 2017) and the CANDELS Lyman-alpha Emission at Reionization (CLEAR; Estrada-Carpenter et al. 2019) programs over the XDF region.
2.3. Fiducial SED Template and Dust Temperature Evolution

The purpose of this subsection is to summarize our approach in modeling the far-IR SED of faint, UV-selected $z = 1.5$–10 galaxies. Having accurate constraints on the overall form of the far-IR SED for these galaxies is potentially important for interpreting far-IR continuum observations of the distant universe to quantify the dust-obscured SFRs. The goal of this subsection will be to use a variety of published observations from the literature to motivate the approach we will utilize throughout the rest of this manuscript.

As is common practice (e.g., Casey 2012), we will adopt a modified blackbody (MBB) form to model the far-IR spectral energy distributions of galaxies (e.g., Casey 2012), with a dust emissivity power-law spectral index of $\beta_d = 1.6$, which is toward the center of the range of values (1.5–2.0) frequently found in the observations (Eales et al. 1989; Klaas et al. 1997). MBB SEDs have the advantage of being relatively simple in form, but are known to show less flux at mid-IR wavelengths than galaxies with a prominent mid-IR power-law component. Fortunately, the impact of such differences on the conversion factors from the energy distributions of galaxies to their equivalent values using an emissivity index of $\beta_e = 0$ is likely a consequence of differences in the 1.2mm flux densities we observe and the total IR luminosity is relatively modest (i.e., factors of $\lesssim 1.5$; see, e.g., Casey et al. 2018), especially relative to other issues like the dust temperature.

Characterizing the evolution of the dust temperature as a function of redshift is challenging due to both selection bias and the significant dependence the dust temperature can show on other quantities like the bolometric luminosity, specific star formation, and the wavelength where dust becomes opaque (e.g., Magnelli et al. 2014; Liang et al. 2019; Ma et al. 2019) which are arguably larger and more significant than the impact of redshift on the dust temperature.

Nevertheless, there have been multiple studies looking at the evolution of dust temperature in galaxies with redshift for fixed values of the bolometric luminosity (e.g., Béthermin et al. 2015; Schreiber et al. 2018). One particularly comprehensive recent study on this front has been by Schreiber et al. (2018), who consider the apparent evolution in dust temperatures from $z \sim 4$ to $z \sim 0$ using stacks of the available Herschel observations.

In Figure 1, we present the same observations that Schreiber et al. (2018) consider, and then add earlier results from Béthermin et al. (2015) to their constraints. Finally, we also include the dust temperature measurements obtained by Pavesi et al. (2016) on a $z \sim 5.25$ galaxy, by Knudsen et al. (2017) on a $z \sim 7.5$ galaxy, by Hashimoto et al. (2019) on a $z = 7.15$ galaxy, by Harikane et al. (2020) on two $z \sim 6.1$ galaxies, by Balx et al. (2020) on the Tamura et al. (2019) $z = 8.31$ galaxy, by Faisst et al. (2020) on four $z \sim 5.5$ galaxies, and by Béthermin et al. (2020) on stacks of $z = 4$–5 and $z = 5$–6 galaxies, as well as the median dust temperatures measured by Strandet et al. (2016) on their sample of bright South Pole Telescope (SPT) sources. Each of these temperature measurements is reported to be corrected for the impact of cosmic microwave background (CMB) radiation (da Cunha et al. 2013).

To make the present dust temperature measurements in Figure 1 as consistent as possible, all measurements have been converted to their equivalent values using an emissivity index $\beta_d$ of 1.6 and using the light-weighted dust temperatures (converting the Schreiber et al. 2018 temperatures from the mass-weighted temperatures to light-weighted temperatures using their Equation (6)). Pursuing a joint fit to all dust temperature measurements in Figure 1, we derive the following relationship between dust temperature and redshift:

$$T_d[K] = (34.6 \pm 0.3) + (3.94 \pm 0.26)(z - 2).$$

The best-fit evolution we derive for the dust temperature is higher than what Schreiber et al. (2018) derive ($T_d[K] = (32.9 \pm 2.4) + (4.60 \pm 0.35)(z - 2)$) due to our use of light-weighted dust temperatures where the dust temperatures are higher. Our best-fit relation for the temperature evolution does, however, evolve slightly less steeply with redshift, largely as a result of our inclusion of constraints from SPT sources, the four Faisst et al. (2020) $z \sim 5.5$ galaxies, and the new Béthermin et al. (2020) stack constraints for $z = 4$–6 galaxies. This best-fit evolution is also not especially dissimilar from the trends found in theoretical models such as those by Narayanan et al. (2018), Liang et al. (2019), and Ma et al. (2019). In the Narayanan et al. (2018) results, the dust temperature increases from 40–50 K in galaxies at $z \sim 2$–3 galaxies to 55–70 K at $z \sim 6$–7. In Liang et al. (2019) and Ma et al. (2019), the evolution in dust temperature expected on the basis of the evolution of the MASSIVEFIRE sample is $(1 + z)^{0.36 \pm 0.06}$ (their Table 2), similar to that implied by Equation (1) above.

Despite the clear evolution in temperature found here and earlier by Béthermin et al. (2015) and Schreiber et al. (2018), other recent studies find no less evolution in dust temperature with redshift. For example, Ivison et al. (2016) infer only $\sim 50\%$ as much evolution in the dust temperature as we find, while other studies, e.g., Dudzevičiūtė et al. (2020), find no significant evolution in the dust temperature of galaxies with redshift when a purely luminosity-limited sample is studied (see also Strandet et al. 2016). Dudzevičiūtė et al. (2020) have argued that the apparent temperature evolution that studies such as Schreiber et al. (2018) have found is likely a consequence of luminosity variations in that study. Given this, we also consider

![Figure 1](image-url)
there being less evolution of the dust temperature of galaxies with cosmic time than in our fiducial models.

Assuming that the effective dust temperature of obscured star formation in $z \sim 1.5$–10 galaxies follows the same evolution as given by Equation (1), we can derive the limiting dust-obscured SFR we would be able to detect as a function of redshift from our program. Adopting a modified blackbody form for the SED shape described at the beginning of this subsection and accounting for the impact of the CMB (e.g., Section 3.1.1 of da Cunha et al. 2013), we estimate that we should be able to tentatively detect at 4$\sigma$ any star-forming galaxy at $z > 2$ with an IR luminosity (8–1000 $\mu$m rest frame) in excess of $6.8 \times 10^{10} L_\odot$ at $z \sim 2$, $9.0 \times 10^{10} L_\odot$ at $z \sim 3$, and $11.2$–28.4 $\times 10^{10} L_\odot$ at $z \sim 4$–10. We verified that use of potentially more realistic far-IR SED templates than a modified blackbody form, following, e.g., Álvarez-Márquez et al. (2016) with a mid-IR power law, yields similar 1.2 mm to IR luminosity conversion factors (see also Appendix A of Fudamoto et al. 2020a).

Adopting the Kennicutt (1998) conversion between IR luminosity and the SFR, these limits translate to 4$\sigma$ limits on the obscured SFRs of 6.8 $M_\odot$ yr$^{-1}$, 9.0 $M_\odot$ yr$^{-1}$, and 11.2–28.4 $M_\odot$ yr$^{-1}$, respectively, at these redshifts. If we instead allow for much less evolution in the dust temperature, such that the typical dust temperature at $z \sim 4$–8 is 35 K, the 4$\sigma$ limits from ASPECS translates to limits on the obscured SFRs of 4–5 $M_\odot$ yr$^{-1}$.

In Table 1, we provide these limiting luminosities and SFRs in tabular form, while providing for context these limits for $M_\odot$ yr$^{-1}$ galaxies for examina-

2.4. Selections of $z = 1.5$–10 Galaxies

In constructing samples of $z = 1.5$–10 galaxies for examination with the ASPECS ALMA data, we utilize both Lyman-break selection criteria as well as photometric redshift selection to ensure our samples are as comprehensive as possible.

To ensure consistency with earlier results from our pilot study (Bouwens et al. 2016), we have adopted essentially identical color–color and photometric redshift selection criteria to those applied in Bouwens et al. (2016). $z = 1.5$–3.5 sources are identified using the same Lyman-break color criteria we had earlier used in Bouwens et al. (2016) and identified by running the EAZY photometric redshift code (Brammer et al. 2008) on our own HST WFC3/UVIS, ACS, and WFC3/IR photometric catalogs. Our $z \sim 2$ and $z \sim 3$ color criteria are as follows:

$z \sim 2$: ($U_{274} - U_{336} > 1$) \& ($U_{336} - B_{435} < 1$)\& ($V_{606} - Y_{105} < 0.7$) \& ($S/N(UV_{225}) < 1.5$),

$z \sim 3$: ($U_{336} - B_{435} > 1$) \& ($B_{435} - V_{606} < 1.2$)\& ($i_{775} - Y_{105} < 0.7$) \& ($\chi^2_{UV_{225}UV_{125}} < 2$)

where $\&$, $\|$ represents the logical AND, OR symbols, $\chi^2$ is the $\chi^2$ parameter defined in Bouwens et al. (2011), and signal-to-noise ratio in our smaller scalable apertures, respectively. We also made use of the photometric catalog of Rafelski et al. (2015) and included those sources in our samples, if not present in the other selections.

Our $z = 4$–8 samples are drawn from the Bouwens et al. (2015) samples and include all $z = 3.5$–8.5 galaxies located over the 4.2 arcmin$^2$ ASPECS region. The Bouwens et al. (2015) samples were based on the deep optical ACS and WFC3/IR observations within the HUDF. $z = 4$–8 samples were constructed by applying Lyman-break-like color criteria to the XDF reduction (Illingworth et al. 2013) of the HUDF. Those criteria are the following for our $z \sim 4, 5, 6, 7$, and 8 selections:

$z \sim 4$: ($B_{435} - V_{606} > 1$) \& ($i_{775} - J_{125} < 1$)\& ($B_{435} - V_{606} > 1.6(i_{775} - J_{125}) + 1$),

$z \sim 5$: ($V_{606} - i_{775} > 1.2$) \& ($z_{850} - H_{160} < 1.3$)\& ($V_{606} - i_{775} > 0.8(z_{850} - H_{160}) + 1.2$),

$z \sim 6$: ($i_{775} - z_{850} > 1.0$) \& ($Y_{105} - H_{160} < 1.0$)\& ($i_{775} - z_{850} > 0.77(Y_{105} - H_{160}) + 1.0$),

$z \sim 7$: ($z_{850} - Y_{105} > 0.7$) \& ($J_{125} - H_{160} < 0.45$)\& ($z_{850} - Y_{105} > 0.8(J_{125} - H_{160}) + 0.7$),

$z \sim 8$: ($Y_{105} - J_{125} > 0.45$) \& ($J_{125} - H_{160} < 0.5$)\& ($Y_{105} - J_{125} > 0.75(J_{125} - H_{160}) + 0.525$).

The six galaxies in our $z = 9$–10 samples are identified by applying the following $Y_{105}/J_{125}$-dropout Lyman-break color criteria to the available HST data:

$z \sim 9$: (($Y_{105} - H_{160}) + 2(J_{125} - H_{160}) > 1.5$)\& (($Y_{105} - H_{160}) + 2(J_{125} - H_{160}) > 1.5 + 1.4(J_{125} - H_{160})$)\& ($J_{125} - H_{160} < 0.5$)\& ($J_{125} - H_{160} < 1.2$),

$z \sim 10$: ($J_{125} - H_{160} > 1.2$) \& (($H_{160} - [3.6] < 1.4$)\& ($S/N([3.6]) < 2$).

Selected sources are required to be undetected ($<2\sigma$) in all HST passbands blueward of the break, both individually and in a stack. Potential stars are excluded from our selection using the measured SExtractor (Bertin & Arnouts 1996) stellarity criterion.

To ensure that our color criteria were not included, for galaxies which are likely passive we adopt a $UVJ$-like criterion (Williams et al. 2009) which allow us to exclude passive galaxies from our $z \geq 1.5$ selection of star-forming galaxies. Specifically, we adopt the prescription given in Pannella et al. (2015):

($U - V < 1.3$) \& ($V - J > 1.6$)\& ($U - V < 0.88(V - J > 0.59$),

which is very similar to the prescription given in Williams et al. (2009). Application of this criteria to our $z \sim 1.5$–10 selection results in the exclusion of just one source from our selection.

The $z \sim 2$, 3, 4, 5, 6, 7, 8, 9, and 10 selections we consider over the ASPECS footprint include 447, 203, 395, 139, 94, 54, 24, 4, and 2 distant sources, respectively (Table 2). The expected contamination levels in these color-selected samples by lower-redshift galaxies estimated to be on the order of 3%–8% (e.g., Bouwens et al. 2015). Sources in our selection have apparent magnitude in the UV-continuum extending from 23.5–30.5 mag (Figure 2 (left panel)).

2.5. UV-continuum Slopes $\beta$ and Stellar Masses for Individual Sources over ASPECS

Based on an abundance of previous work, it is well known that the IRX is correlated with the measured UV-continuum

\[ \text{IRX} = \beta \times \text{UV} \]

where $\beta$ is the UV slope, and $\text{UV}$ is the UV luminosity. The IRX is defined as the ratio of the IR luminosity to the UV luminosity, and is a measure of the relative amount of dust in a galaxy. The UV slope $\beta$ is defined as the ratio of the UV luminosity to the IR luminosity, and is a measure of the relative amount of young stars in a galaxy. The IRX is a useful diagnostic for characterizing the star formation activity in galaxies.

In Table 2, we provide the UV slopes $\beta$ and stellar masses $M_*$ for our selected sources. The UV slopes $\beta$ range from -1.5 to 2.5, with most sources having $\beta$ between -1 and 1. The stellar masses $M_*$ range from $10^8$ to $10^11$ $M_\odot$, with most sources having $M_* > 10^9$ $M_\odot$. The results are consistent with expectations for star-forming galaxies at these redshifts.
Table 1

4σ Sensitivity Limits for Our Probe of Obscured Star Formation from Individual $z \gtrsim 1.5$ Galaxies and the Dependence on SED

| Far-IR SED Model | $z\sim2$ | $z\sim3$ | $z\sim4$ | $z\sim5$ | $z\sim6$ | $z\sim7$ | $z\sim8$ | $z\sim9$ | $z\sim10$ |

Notes.

$^a$ Using Equation (1).

$^b$ Standard modified blackbody form (e.g., Casey 2012) with a dust emissivity power-law spectral index of $\beta_d = 1.6$ (Eales et al. 1989; Klaas et al. 1997).

The Kennicutt (1998) conversion factor from IR luminosity to SFR is adopted.

slopes of galaxies (e.g., Meurer et al. 1999) and also the stellar mass (e.g., Whitaker et al. 2017).

For each of the sources over ASPECS, we derive a UV-contiuum slope $\beta$ fitting the HST photometry in various bands probing the UV-contiuum to a power law $f_{\lambda}(\lambda/1600 \text{ Å})^\beta$ to derive a mean flux at $\sim 1600 \text{ Å}$ and also a spectral slope $\beta$. Flux measurements in bands that could be impacted by IGM absorption or rest-frame optical $\gtrsim 3500 \text{ Å}$ light are excluded. The inclusion of photometric constraints on the UV-contiuum even to $\sim 3000 \text{ Å}$ is expected to have little impact on the derived $\beta$ given the general power-law-like shape of the UV continuum (e.g., see Appendix A in Wilkins et al. 2016). Due to the limited wavelength leverage available to derive UV-contiuum sources for sources at $z \sim 8$–10, we take the UV-contiuum slope $\beta$ to be uniformly $-2.2$ consistent with the results of Bouwens et al. (2014a).

As in other work (e.g., Sawicki & Yee 1998; Brinchmann & Ellis 2000; Papovich et al. 2001; Labbé et al. 2006; González et al. 2014), we estimate stellar masses for individual sources in our samples by modeling the observed photometry using stellar population libraries and considering variable (or fixed) star formation histories, metallicities, and dust content.

For $z \sim 1.5$–10 sources in our catalogs, we make use of the publicly-available code FAST (Kriek et al. 2009) to perform this fitting. We assume a Chabrier (2003) IMF, a metallicity of 0.2 $Z_\odot$, a stellar population age from 10 Myr to the age of the universe, and allow the dust extinction in the rest-frame $V$ to range from 0 to 2 mag, which we acknowledge may be inadequate for some especially dust-rich galaxies (e.g., Simpson et al. 2017). We assume an $e^{-t/\tau}$ star formation history and allow the $\tau$ parameter to have any value from 1–100 Gyr. Our fixing the fiducial metallicity to 0.2 $Z_\odot$ is motivated by studies of the metallicity of individual $z \sim 2$–4 galaxies (Pettini et al. 2000) or as predicted from cosmological hydrodynamical simulations (Finlator et al. 2011; Wise et al. 2012). While the current choice of parameters can have a sizeable impact on inferred quantities like the age of a stellar population (changing by $>0.3$–0.5 dex), these choices typically do not have a major impact ($>0.2$ dex) on the inferred stellar masses.

Table 2

| Redshift | Selection Criterion | Number of Sources | References |
|---------|---------------------|-------------------|------------|
| $z \sim 2$ | $UV_{275}$-dropout or $1.5 < z_{phas} < 2.5$ | 447 | R15/This work |
| $z \sim 3$ | $U_{336}$-dropout or $2.5 < z_{phas} < 3.5$ | 203 | R15/This work |
| $z \sim 4$ | $B_{435}$-dropout or $3.5 < z_{phas} < 4.5$ | 395 | B15/This work |

| Total | | 1362 | |

References. B15 = Bouwens et al. (2015), R15 = Rafelski et al. (2015).

In deriving the stellar masses for individual sources, we use made of flux measurements from 11 HST bands ($UV_{225}$, $UV_{275}$, $U_{336}$, $B_{435}$, $V_{606}$, $i_{775}$, $z_{850}$, $Y_{105}$, $J_{125}$, $H_{140}$, $H_{160}$), one band in the near-IR from the ground ($K_s$), and four Spitzer/IRAC bands (3.6 μm, 4.5 μm, 5.8 μm, and 8.0 μm). The HST photometry we use for estimating stellar masses is derived applying the same procedure as used for selecting our $z \sim 1.5$–3.5 Lyman-break galaxies (LBG) samples (see Section 2.2).

A modest correction is made to the Spitzer/IRAC 3.6 μm and 4.5 μm photometry to account for the impact of nebular emission lines on the observed IRAC fluxes. Specifically, the 3.6 μm and 4.5 μm band fluxes of galaxies in the redshift ranges $z = 3.8$–5.0 and $z = 5.1$–6.6, respectively, are reduced by 0.32 mag and 0.35 mag, respectively, to remove the contribution of the Hα+[N II] emission lines to the broadband fluxes. A 0.32 mag and 0.35 mag correction is appropriate for a
rest-frame equivalent width (EW) of \( \sim 500 \text{ Å} \) and \( \sim 540 \text{ Å} \), respectively, for the H\( \alpha \)+[N\( \text{II} \)] emission lines, consistent with most determinations of the H\( \alpha \)+[N\( \text{II} \)] emission line EW over the range \( z = 3.8-5.4 \) (Stark et al. 2013; Máról-Queraltó et al. 2016; Faisst et al. 2016; Smit et al. 2016; Rasappu et al. 2016).

For galaxies in the redshift ranges \( z = 5.4-7.0 \) and \( z = 7.0-9.1 \), the measured fluxes in the 3.6 \( \mu \text{m} \) and 4.5 \( \mu \text{m} \) bands are reduced by 0.5 mag. A 0.5 mag correction is appropriate for a rest-frame EW of \( \sim 680 \text{ Å} \) for the H\( \alpha \)+[N\( \text{II} \)] emission lines, consistent with most determinations of the H\( \alpha \)+[N\( \text{II} \)] emission line EW over the range \( z = 3.8-5.4 \) (Labbé et al. 2013; Smit et al. 2014, 2015; Faisst et al. 2016; Endsley et al. 2020). The fiducial stellar mass estimates we derive using FAST are typically \( \sim 0.1 \) dex lower than using other stellar population codes like MAGPHYS and PROSPECTOR (see Appendix A).

The middle panel of Figure 2 illustrates the effective range in stellar mass probed by our \( z = 1.5-10 \) sample. Most sources from our HUDF \( z = 1.5-10 \) sample have stellar masses in the range \( 10^{7.5-10^{10}} \text{ M}_\odot \). The most massive sources probed by our program extend to \( 10^{11.5} \text{ M}_\odot \). Beyond the stellar mass itself, Figure 2 also illustrates the range in UV-continuum slope \( \beta \) probed by our samples (see Section 3.1 for details on how \( \beta \) is derived). Since the measured \( \beta \) has been demonstrated to be quite effective in estimating the IRX for lower-redshift UV-selected samples (e.g., M99; Reddy et al. 2006; Daddi et al. 2007), it is useful for us to probe a broad range in \( \beta \). As can be seen from Figure 2, our samples probe the range \( \beta \sim 1-2.5 \) quite effectively.

3. Results

In this section, we quantify the IRX of star-forming galaxies in the intermediate- to high-redshift universe \( z > 1.5 \). As in previous work (e.g., Meurer et al. 1999; Álvarez-Márquez et al. 2016; Whitaker et al. 2017) we define the IRX to be

\[
\text{IRX} = \frac{L_{\text{IR}}}{L_{\text{UV}}}
\]

where \( L_{\text{IR}} \) is the infrared luminosity of galaxies (including all rest-frame emission from 8 \( \mu \text{m} \) to 1000 \( \mu \text{m} \)) and \( L_{\text{UV}} \) is the UV luminosity of galaxies, which we take to be \( v f_\nu \). \( v \) is evaluated at \( c/\lambda_{6000} \text{ Å} \) in computing the UV luminosities \( L_{\text{UV}} \) of sources.

3.1. Expected Number of Continuum Detections from \( z \sim 1.5 \) to 10 Galaxies within ASPECS

Thanks to the limited evolution seen in the IRX versus stellar mass and IRX versus \( \beta \) results over the entire redshift range \( z \sim 3 \) to \( z \sim 0 \) (Reddy et al. 2006; Whitaker et al. 2017; Fudamoto et al. 2020a), we might expect these relations to be at least approximately valid to even higher redshifts.

Before looking in detail at which sources show continuum detections and what their properties are, let us briefly calculate how many sources we would expect to detect based on published IRX versus stellar mass and IRX versus UV-continuum slope \( \beta \) relations. Given the limited evolution in these relations, we expect the predicted results to be reasonably accurate in estimating the overall numbers from our program. For our baseline IRX–stellar mass \( M \) relation, we take the relation derived in our pilot program (Appendix A from Bouwens et al. 2016):

\[
\log_{10} \text{IRX}_{M,0} = \log_{10} M - 9.17.
\]

For our baseline IRX–\( \beta \) relation, we make use of the consensus low-redshift relation derived in Appendix B based on the following three studies (Overzier et al. 2011; Takeuchi et al. 2012; Casey et al. 2014). The relation we derive is the following:

\[
\text{IRX}_{\beta=0} = 1.7(10^{0.4(1.86(\beta+1.85))-1}).
\]

The IRX implied by the above relation are \( \approx 0.5 \) times that of the Meurer et al. (1999) relation. Equivalent expressions for a Reddy (similar to Calzetti et al. 2000) and SMC-like dust law are the following:

\[
\text{IRX}_{\text{Reddy}} = 1.7(10^{0.4(1.84(\beta+1.85))-1})
\]

\[
\text{IRX}_{\text{SMC}} = 1.7(10^{0.4(1.84(\beta+1.85))-1})
\]
and

\[
\text{IRX}_{\text{SMC}} = 1.7 \times 10^{0.4(1.1(\beta + 1.85))} - 1.
\] (6)

Based on the above relations and observed UV fluxes, we can compute the equivalent flux at an observed wavelength of 1.26 mm adopting a modified blackbody form with a dust emissivity power-law spectral index of \(\beta_d = 1.6\) and dust temperature given by Equation (1). To account for the impact of the CMB at \(z \sim 1.5-10\) on the observed flux densities we would measure, we multiply the predicted flux (before consideration of CMB effects) by \(C_\nu\)

\[
C_\nu = \left[ 1 - \frac{B_\nu(T_{\text{CMB}}(z))}{B_\nu(T_e(z))} \right],
\] (7)

following prescriptions given in da Cunha et al. (2013).

Using the above procedure, we calculated the expected flux for our entire sample of 1362 \(z \sim 1.5-10\) galaxies identified over the 4.2 arcmin\(^2\) ASPECS footprint alternatively making use of the consensus IRX–stellar mass relation from Bouwens et al. (2016), our consensus low-redshift IRX–\(\beta\) relation, and also a SMC-like IRX–\(\beta\) relation (Equations (3)–(6)). Fifteen, 28, and eight sources, respectively, are predicted to show >4\(\sigma\) detections in the ASPECS observations in the 1.2 mm continuum. Assuming a fixed dust temperature of 35 K, the predicted numbers would be 27, 42, and 11, respectively. Figure 3 shows the predicted IR luminosities versus redshift using either the aforementioned IRX–stellar mass relation (left) or the IRX–\(\beta\) relation (right) for our fiducial dust temperature model. The solid red and dotted lines show the 4\(\sigma\) IR luminosity limit we probe with the ASPECS data set adopting the fiducial dust temperature model given in Equation (1) (solid red line) and assuming the dust temperature remains fixed at 35 K for all of cosmic time (dotted red line).

### 3.2. Continuum Detections of Individual Sources at 1.2 mm

Examination of the 1362 \(z \sim 1.5-10\) galaxies over our sensitive ASPECS mosaic shows that 18 of these galaxies are detected at >4\(\sigma\) in the 1.2 mm continuum images. We use the flux densities and uncertainties that González-López et al. (2020) derive for each source from the 1.2 mm continuum images. González-López et al. (2020) make use of flux density measurements made from the tapered images, allowing for a more complete account of the total dust-continuum flux density in sources, many of which are spatially extended. The coordinates and source properties of the continuum detected sources are provided in Table 3. 1.2 mm continuum images of the 4\(\sigma\)-detected sources are presented in Figure 4 and shown with respect to the HST and Spitzer/IRAC images.

The IR luminosities we estimated based on our far-IR SEDs and fiducial dust temperature evolution (Equation (1)) are presented in Table 3 and range from \(1.4 \times 10^{11} L_\odot\) to \(2.6 \times 10^{12} L_\odot\). Aravena et al. (2020), in a separate analysis of these same sources using SED fits from MAGPHYS, find the range to be \(1.1 \times 10^{11} L_\odot\) to \(3.4 \times 10^{12} L_\odot\). Our derived IR luminosities are just 0.01 dex higher in the mean than those employed by Aravena et al. (2020), demonstrating that the modified blackbody form we utilize here produces IR luminosities very similar to SED analyses that include a mid-IR power law.

The total number of >4\(\sigma\) detections in the \(z \sim 1.5-10\) galaxies found over the ASPECS footprint is 18. In Section 3.1, we had predicted that 15, 28, and 8 sources would be found from this selection using the consensus IRX–stellar mass relationship, the consensus low-redshift IRX–\(\beta\) relationship, and an SMC-like IRX–\(\beta\) relationship. If in our use of the IRX–\(\beta\) relationship we only consider those sources with stellar masses greater than \(10^{9.5} M_\odot\), the predicted number of 4\(\sigma\)
detected. It is therefore useful to stack the continuum observations from ASPECS to derive constraints on their dust-continuum properties. We consider various subdivisions of our samples in terms of the physical properties.

For sources included in the stack, the ALMA continuum maps of the relevant sources are mapped onto the same position and stacked in the image plane, weighting each in proportion to the expected 1.2 mm continuum signal divided by the noise (per beam). We derive a flux density from the stack based on a convolution of the image stack [3''3 × 3''3 aperture] with the primary beam. Individually undetected sources are assumed to be unresolved at the resolution of our observations.

### 3.3. Stacked Constraints on the Infrared Excess

Fainter, lower-mass sources in our selections are not sufficiently bright in the dust continuum to be individually detected. It is therefore useful to stack the continuum observations from ASPECS to derive constraints on their dust-continuum properties. We consider various subdivisions of our samples in terms of the physical properties.

For sources included in the stack, the ALMA continuum maps of the relevant sources are mapped onto the same position and stacked in the image plane, weighting each in proportion to the expected 1.2 mm continuum signal divided by the noise squared (per beam). We derive a flux density from the stack based on a convolution of the image stack [3''3 × 3''3 aperture] with the primary beam. Individually undetected sources are assumed to be unresolved at the resolution of our observations.

#### 3.3.1. Infrared Excess versus Stellar Mass

We first look at the average IRX of $z = 1.5–10$ galaxies as a function of stellar mass. We consider six different bins of stellar mass: $>10^{10.75} M_{\odot}$, $10^{10.25}–10^{10.75} M_{\odot}$, $10^{9.75}–10^{10.25} M_{\odot}$, $10^{9.25}–10^{9.75} M_{\odot}$, $10^{8.75}–10^{9.25} M_{\odot}$, and $<10^{8.75} M_{\odot}$. For these stacks, we weight sources according to the inverse square of the noise [in $\mu$Jy], i.e., $\sigma(f_{1.2\text{mm}})^{-2}$. 

---

\text{a similar conclusion. It is clear that stellar mass is a particularly useful predictor of} \\
\text{IR luminosity over a wide range in redshift.}
\end{align*}

Our stack results are presented in Figure 8 for both our
z = 1.5–3.5 and z = 3.5–10 samples, including both the
individually detected and undetected sources. Galaxies in our
10^{10.75}–10^{11.25} M_\odot mass bin are detected at 10σ, while sources in
the 10^{10.25}–10^{10.75} M_\odot bin only show a tentative 2σ detection.

\begin{align*}
\text{Our stack results for star-forming galaxies which are individually undetected (<4σ) are presented in} \\
\text{Figure 9.}
\end{align*}

Our z = 1.5–3.5 stack results provide us with the highest
S/N results to derive a dependence of the IRX on stellar mass.
In quantifying the dependence, we made use of the power-law relation

\begin{align*}
\text{IRXM} = (M/M_\odot)^\alpha 
\end{align*}

where M_\odot is the characteristic stellar mass for significant IR
emission (L_{IR} = L_{UV}) and α gives the power by which the IRX
depends on mass. We then fit our z = 1.5–3.5 stacked IRX
measurements to this relation and arrived at a best-fit value for
M_\odot and α of 10^{0.15±0.18} M_\odot and 0.97±0.17, respectively. The
best-fit relation is shown in both the left and right panels of Figure 8
with the light-red shaded region. Broadly, our z = 1.5–3.5
results are consistent with the consensus relation that we derived in our earlier analysis based on results in the literature (Bouwens et al. 2016).

At z = 3.5–10, our stack results for the IRX show a clear
detection in the highest stellar mass bin and a tentative 2σ detections in the third highest stellar mass bin, i.e.,
10^{9.25}–10^{9.75} M_\odot, while at lower masses, there is still no
detection in our stack results. Our new stack results for the
IRXs at z = 3.5–10 seem consistent with what we derive at lower redshifts. Previously, Pannella et al. (2015) had found no strong evidence for evolution in the IRX–stellar mass relation to z ∼ 3.5, and Whitaker et al. (2017) found this same lack of evolution to z ∼ 3. From first principles, one might expect

\begin{align*}
\text{To this end, we used the 109.25} \\
\text{ detection in our stack results. Our new stack results for the} \\
\text{three different stacks of all 1253 z = 1.5–10 sources with stellar mass estimates <10^{9.25} M_\odot over our ASPECS footprint.} \\
\text{Our first stack weights sources by their UV flux, our second stack weights sources by their estimated stellar mass, and our} \\
\text{third stack weights sources equally (left, center, and right panels, respectively). None of the stacks show a significant detection, and in our unweighted stack, the mean continuum flux density is −0.1 ± 0.4 ± 0.4 μJy beam$^{-1}$. Even weighting sources in the stack by the measured UV-continuum slope β fails to result in a significant detection. This demonstrates, rather dramatically, that faint, UV-selected galaxies show essentially no dust-continuum emission (see also Carvajal et al. 2020). Converting this flux density constraint to a SFR for a galaxy at z ∼ 4, we derive a SFR of 0.0 ± 0.1 M_\odot yr$^{-1}$.} 
\end{align*}
The estimated stellar masses for sources from CANDELS are based on the Calzetti-like dust curve, which is individually undetected in Appendix C.

As a result of the redshift values for these quantities (e.g., Equation (4)). If we instead take $\beta_{\mathrm{int}} = -2.23$ as been conventional (following Meurer et al. 1999), the $A_{\mathrm{UV}}/\beta$ we recover is $1.48^{+0.09}_{-0.11}$. In our pilot study, our best-fit determination for $A_{\mathrm{UV}}/\beta$ is $1.26^{+0.27}_{-0.36}$ when taking $\beta_{\mathrm{int}}$ equal to $-2.23$. For a $\beta_{\mathrm{int}} = -2.30$, we recover $A_{\mathrm{UV}}/\beta$ equal to $1.42^{+0.09}_{-0.11}$.

For lower-mass ($<10^{10.5} \, M_\odot$) $z \sim 1.5$–3.5 galaxies found over ASPECS, significant ALMA continuum flux is found in two of the three $\beta$ bins we consider. Fixing $\beta_{\mathrm{int}}$ to be the same as for the higher-mass galaxies, we find a best-fit value for $A_{\mathrm{UV}}/\beta$ of $1.12^{+0.31}_{-0.36}$. This is most consistent with an SMC-like dust curve, but is nevertheless consistent with our constraints on $A_{\mathrm{UV}}/\beta$ value in the higher mass $>10^{10.5} \, M_\odot$ bin.

We now look at the constraints we can set on the IRX–$\beta$ relationship at $z \sim 3.5$–10. We focus on sources with the highest stellar masses, i.e., $>10^{10.25} \, M_\odot$ to minimize the impact of intrinsically blue, lower-mass sources scattering to redder colors (see Section 3.1.1 from Bouwens et al. 2016). Our $z \sim 3.5$–10 stack results for sources shows prominent detections in the redder two $\beta$ bins, one at $-0.8$ and 1.6. Those two detections imply very different IRX–$\beta$ relationships. Fixing the value of $\beta_{\mathrm{int}}$ to be $-2.23$ and fitting to two bluest $\beta$ bins plus the $\beta \sim -0.8$ bin, we derive a $A_{\mathrm{UV}}/\beta$ value of $2.27$. By contrast, if we fit to the two bluest $\beta$ bins plus the $\beta \sim 1.6$ bin, we derive a $A_{\mathrm{UV}}/\beta$ value of $0.63$. Given how different the two relations are and the fact that there are only two significant detections at $z > 3.5$ we can use from ASPECS, perhaps it is best for us simply to quote our $z = 3.5$–10 results as the range spanned by these two relations. As this range includes both Reddy/Calzetti-like and SMC-like dust relations, the ASPECS data provides us with very little information on the IRX–$\beta$ relation evolution.

### 3.3.3. Summary of Stack Results

Our convenient summary of our main stack results as a function of stellar mass, redshift, and $\beta$ is provided in Table 4. For a more detailed breakdown of these stack results and comparison with expectations, we refer the interested reader to Appendix C.

### 3.4. Infrared Excess as a Bivariate Function of Stellar Mass and $\beta$

#### 3.4.1. Correlation with Stellar Mass and UV-continuum Slope $\beta$

Having looked at the correlation of the IRX with the stellar mass and UV-continuum slope $\beta$, it is interesting to try to link these relations based on both the empirical correlation of these

$$IRX_\beta = 1.7 \times 10^{0.4(d_{\mathrm{UV}}/\beta)(\beta - \beta_{\mathrm{int}})} - 1,$$

instead of just deriving constraints on $d_{\mathrm{UV}}/\beta$ as in our previous analysis. Our maximum-likelihood derived values for $d_{\mathrm{UV}}/\beta$ and $\beta_{\mathrm{int}}$ are $1.81^{+0.18}_{-0.14}$ and $-1.86^{+0.14}_{-0.10}$ and presented in Table 5. The $d_{\mathrm{UV}}/\beta$ we derive is similar to the Calzetti or Reddy value, i.e., 1.97 or 1.84. Meanwhile, the $\beta_{\mathrm{int}} = -2.23$ implicit in the Meurer et al. (1999) formulation, but also redder than what might be expected for dust-free galaxies with a constant SFR for 100–500 Myr (e.g., as in Reddy et al. 2018). Both the $d_{\mathrm{UV}}/\beta$ and $\beta_{\mathrm{int}}$ we derive are consistent with the consensus low-redshift values for these quantities (e.g., Equation (4)). If we instead take $\beta_{\mathrm{int}} = -2.23$ as has been conventional (following Meurer et al. 1999), the $d_{\mathrm{UV}}/\beta$ we recover is $1.48^{+0.09}_{-0.11}$. In our pilot study, our best-fit determination for $d_{\mathrm{UV}}/\beta$ is $1.26^{+0.27}_{-0.36}$ when taking $\beta_{\mathrm{int}}$ equal to $-2.23$. For a $\beta_{\mathrm{int}} = -2.30$, we recover $d_{\mathrm{UV}}/\beta$ equal to $1.42^{+0.09}_{-0.11}$.

For lower-mass ($<10^{10.5} \, M_\odot$) $z \sim 1.5$–3.5 galaxies found over ASPECS, significant ALMA continuum flux is found in two of the three $\beta$ bins we consider. Fixing $\beta_{\mathrm{int}}$ to be the same as for the higher-mass galaxies, we find a best-fit value for $d_{\mathrm{UV}}/\beta$ of $1.12^{+0.31}_{-0.36}$. This is most consistent with an SMC-like dust curve, but is nevertheless consistent with our constraints on $d_{\mathrm{UV}}/\beta$ value in the higher mass $>10^{10.5} \, M_\odot$ bin.

We now look at the constraints we can set on the IRX–$\beta$ relationship at $z \sim 3.5$–10. We focus on sources with the highest stellar masses, i.e., $>10^{10.25} \, M_\odot$ to minimize the impact of intrinsically blue, lower-mass sources scattering to redder colors (see Section 3.1.1 from Bouwens et al. 2016). Our $z \sim 3.5$–10 stack results for sources shows prominent detections in the redder two $\beta$ bins, one at $-0.8$ and 1.6. Those two detections imply very different IRX–$\beta$ relationships. Fixing the value of $\beta_{\mathrm{int}}$ to be $-2.23$ and fitting to two bluest $\beta$ bins plus the $\beta \sim -0.8$ bin, we derive a $d_{\mathrm{UV}}/\beta$ value of $2.27$. By contrast, if we fit to the two bluest $\beta$ bins plus the $\beta \sim 1.6$ bin, we derive a $d_{\mathrm{UV}}/\beta$ value of $0.63$. Given how different the two relations are and the fact that there are only two significant detections at $z > 3.5$ we can use from ASPECS, perhaps it is best for us simply to quote our $z = 3.5$–10 results as the range spanned by these two relations. As this range includes both Reddy/Calzetti-like and SMC-like dust relations, the ASPECS data provides us with very little information on the IRX–$\beta$ relation evolution.

### 3.3.2. Infrared Excess versus $\beta$

Stacked results of $z = 1.5$–3.5 and $z = 3.5$–10 sources over our ASPECS footprint are presented as a function of UV-continuum slope $\beta$ in Figure 11 with the large solid circles and 2σ upper limits. Five different bins in $\beta$ are utilized to better map out the trend with UV-continuum slope $\beta$.

Separate stack results are presented for sources with stellar masses $>10^{10.5} \, M_\odot$ (large red circles and downward arrows, respectively) and $<10^{10.5} \, M_\odot$ (large green circles and downward arrows, respectively) to evaluate whether higher-mass galaxies show a different IRX–$\beta$ relationship from lower-mass galaxies. This treatment also ensures that results in the redder, high-mass bins are not impacted by the inclusion of bluer, lower-mass sources (but where the measured UV-continuum slopes $\beta$ are much redder than the actual slopes due to the impact of noise). Figure 12 presents our stack results for star-forming galaxies which are individually undetected ($<4\sigma$). Our IRX–$\beta$ stack results are presented in Table 4 in the main text and Table 11 in Appendix C.

For our highest-mass $z \sim 1.5$–3.5 samples, our stack results lie closest to the Reddy (Calzetti-like) IRX–$\beta$ relations. As in our earlier analysis of the ASPECS pilot data, we formalize this analysis by finding those parameters which best match the stacked IRX results versus $\beta$ and then computing 68% confidence intervals on the derived parameters. Here we derive constraints on both $d_{\mathrm{UV}}/\beta$ and $\beta$ as

$$IRX_\beta = 1.7 \times 10^{0.4(d_{\mathrm{UV}}/\beta)(\beta - \beta_{\mathrm{int}})} - 1, \quad (9)$$
Figure 8. Constraints on the IRX of $z = 1.5–3.5$ (left panel) and $z = 3.5–10$ (right panel) galaxies (large red and blue circles and downward arrows, respectively) obtained by stacking the ALMA 1.2 mm observations available for many individual sources over our 4.2 arcmin² ASPECS footprint. The small filled circles and downward arrows are for sources with a positive 3σ measurement of IRX and 3σ upper limit on IRX, respectively. Upper limits and error bars are 2σ and 1σ, respectively for the stacked points. The thick-shaded gray line shows the consensus dependence of IRX on galaxy stellar mass that had previously been derived for $z \sim 2–3$ galaxies from the literature (Reddy et al. 2010; Whitaker et al. 2014; Álvarez-Márquez et al. 2016) in Bouwens et al. (2016). The light-red shaded region included in the left panel shows the best-fit power-law relation we derive based on our ASPECS IRX measurements at $z = 1.5–3.5$; it is also included in the right panel to facilitate comparisons with the $z = 3.5–10$ results. The black line shows the IRX vs. stellar mass relation found by Whitaker et al. (2017) to hold from $z \sim 0$ to $z \sim 3$. The fiducial results presented here from ASPECS are derived assuming that the dust temperature evolves as in Equation (1), but the dotted black circle and upper limits in the right panel show the impact of assuming no evolution in the dust temperature to $z > 3$ (i.e., fixing $T_d$ at 35 K). Our ALMA stack results suggest that only galaxies with stellar masses in excess of $10^{9.9} M_\odot$ tend to output >50% of their energy at far-IR wavelengths.

This results in

$$\beta = \beta_{\text{int}} + \frac{2.5}{d_{\text{AVS}}} \log_{10} \left( \frac{1}{1.7} (M/M_\odot)^\alpha + 1 \right).$$

(12)

Fixing $\beta_{\text{int}} = -2.3$ and taking the best-fit value we find for $d_{\text{AVS}}$ (i.e., 1.42), we look for the optimal values of $M_s$ and $\alpha$ to capture the observed relationship between stellar mass and UV-continuum slope $\beta$ shown in Figure 7. In deriving this relationship, we segregate sources into those above and below the $\beta$ versus $M$ relation, determine the number of such sources in six distinct regions along the relation, compute the square of the difference in the number of sources on each side for each of the six regions, and then minimize the square of the differences. The best-fit values of $M_s$ and $\alpha$ are $10^{9.07} M_\odot$ and 0.92, respectively. This best-fit relation is included in Figure 7 as the blue line. For comparison, Figure 7 also shows the $\beta$ versus stellar mass relationship derived by McLure et al. (2018). Encouragingly enough, the best-fit value for $M_s$ and $\alpha$ are consistent (at 1σ) with the values we derive from our IRX–stellar mass analysis, i.e., $10^{9.15} M_\odot$ and 0.97$^{+0.17}_{-0.14}$, respectively, demonstrating that the IRX–$\beta$ and IRX–stellar mass relations we derive are essentially equivalent.

two quantities, and on the large samples that now exist from various legacy data sets. Given the significant correlation between the dust content and the metallicity of galaxies and their stellar mass (e.g., Reddy et al. 2010; Pannella et al. 2015), one would expect a strong correlation between the UV-continuum slope of galaxies and their stellar mass, as in fact is observed (e.g., McLure et al. 2018; Carvajal et al. 2020).

For this exercise, we take all the $z = 1.3–2.5$ sources identified over the five CANDELS fields by the 3D-HST team (Skelton et al. 2014) and compare their UV-continuum slopes $\beta$ with their stellar masses derived by PROSPECTOR (Leja et al. 2017, 2019). The results are presented in Figure 7, and it is clear that for sources with stellar masses to $10^{8.8} M_\odot$ the UV-continuum slopes $\beta$ of galaxies generally lie in the range $-2.5$ to $-1.8$. For sources with stellar masses $>10^9$, the UV-continuum slopes $\beta$ show a strong correlation with stellar mass to $10^{11} M_\odot$.

Using the correlations we derive between the IRX and the stellar mass (Section 3.3.1),

$$\log_{10} \text{IRX} = \alpha \log_{10} (M/M_\odot)$$

(10)

and between the IRX and the UV-continuum slope $\beta$ (Section 3.3.2)

$$\log_{10} \text{IRX} = \log_{10} \left( 10^{0.4 \frac{d_{\text{AVS}}}{D^2}} (\beta - \beta_{\text{int}}) - 1 \right) + 0.23.$$  

(11)
The Astrophysical Journal, 902:112 (29pp), 2020 October 20

Alvarez-Márquez et al. (2019) had previously attempted to quantify the IRX as a function of both the UV-continuum slope $\beta$ and stellar mass, as $\log_{10}(\text{IRX}) = (0.51 \pm 0.06)_{\betaUV} + (0.37 \pm 0.08)\log(\mathcal{M}_\odot/\mathcal{M}_\odot) - 1.89 \pm 0.40$. While the functional form Alvarez-Márquez et al. (2019) utilize is different from what we consider, it is interesting to try to compute the logarithmic dependence of IRX on $\beta_{UV}$ and $\log_{10}\mathcal{M}_\odot$ to investigate how similar the results are. For simplicity, we compute the dependence at a $\beta = 0.5$ and $\log_{10}\mathcal{M}_\odot$ of $10^{10.5} \mathcal{M}_\odot$. For the IRX($\beta, M$) function we derive, we compute a $d\log_{10}(\text{IRX})/d\beta$ of 0.18 and a $d\log_{10}(\text{IRX})/d\log_{10}\mathcal{M}_\odot$ of 0.67 versus $0.51 \pm 0.06$ and $0.37 \pm 0.08$ found by Alvarez-Márquez et al. (2019). These relations are in reasonably good agreement, which is encouraging given the differences in approach (the Alvarez-Márquez et al. (2019) relations are based on deep Herschel stacks).

Given the strong correlation between both parameters, where $\Delta \beta = 1.5\Delta\mathcal{M}_\odot$ (see Section 3.4.1), it is also interesting to reformulate the Alvarez-Márquez et al. (2019) IRX relation to be just a single function of $\beta$. We find $d\log_{10}(\text{IRX})/d\beta \sim 0.63$. If we make same change to our bivariate IRX($\beta, M$) relation, we find $d\log_{10}(\text{IRX})/d\beta \sim 0.68$. As with the previous comparison, the two dependencies are similar, which is encouraging given differences in the two approaches.

### 3.5. Predictive Power of Different Estimators for IRX

Before concluding this section, it is useful to summarize the predicted 1.2mm flux densities expected for different $z \gtrsim 1.5$ galaxies over the ASPECS footprint and compare those predictions with the observations. A compilation of the results are presented in Table 6 and include the predicted flux densities using (1) the Meurer et al. (1999) IRX–$\beta$ relation (Equation (B4); Appendix B), (2) the consensus low-redshift IRX–$\beta$ relation (Equation (4)) derived here in Appendix B from literature results, (3) an SMC-like IRX–$\beta$ relation (Equation (6)), (4) the consensus IRX–stellar mass relation (Equation (3)) presented in our previous study (Bouwens et al. 2016), (5) our derived IRX–$\beta$ relation for $>10^{9.5} \mathcal{M}_\odot$, $z \sim 1.5–3.5$ galaxies (Equation (9); Section 3.3.2), (6) our derived IRX–stellar mass relation for $z \sim 1.5–3.5$ galaxies

## Table 4

Inferred IRX vs. Galaxy Stellar Mass and $\beta$ from ASPECS (Assuming the Dust Temperature Evolution Specified in Equation (1))

| Stellar Mass ($M_\odot$) | Number of sources | IRX ($\beta, M$) |
|--------------------------|-------------------|------------------|
| $>10^{10.75}$           | All 6             | 26.99$^{+0.12}_{-0.11}$ |
| $10^{9.75}$–$10^{10.25}$| All 11            | 16.73$^{+0.07}_{-0.07}$ |
| $10^{9.25}$–$10^{9.75}$  | All 33            | 2.23$^{+0.09}_{-0.09}$  |
| $10^{8.75}$–$10^{9.25}$  | All 123           | 0.90$^{+0.05}_{-0.05}$  |
| $<10^{8.75}$             | All 467           | 0.72$^{+0.07}_{-0.07}$  |
| $M > 10^{10.25}$         | All 1             | 19.08$^{+0.10}_{-0.09}$ |
| $10^{9.75}$–$10^{10.25}$ | All 6             | $-0.22^{+0.06}_{-0.06}$ |
| $10^{9.25}$–$10^{9.75}$  | All 31            | 4.12$^{+0.31}_{-0.31}$  |
| $10^{8.75}$–$10^{9.25}$  | All 69            | 0.41$^{+0.50}_{-0.50}$  |
| $<10^{8.75}$             | All 594           | $-0.72^{+0.09}_{-0.09}$ |
| $>10^{9.5}$              | All 4              | $-0.40^{+0.18}_{-0.18}$ |
| $-4.0 < \beta < -1.75$   | 4                 | 0.02$^{+0.16}_{-0.16}$  |
| $-1.75 < \beta < -1.00$  | 16                | 6.54$^{+0.48}_{-0.48}$  |
| $-1.00 < \beta < -0.20$  | 14                | 10.27$^{+0.70}_{-0.70}$ |
| $-0.20 < \beta < 0$      | 4                 | 174.57$^{+1.13}_{-1.13}$ |
| $<10^{9.5}$              | 369               | 0.83$^{+0.17}_{-0.17}$  |
| $-4.0 < \beta < -1.75$   | 369               | 0.83$^{+0.17}_{-0.17}$  |
| $-1.75 < \beta < -1.00$  | 204               | 0.84$^{+0.17}_{-0.17}$  |
| $-1.00 < \beta < 0$      | 34                | 5.57$^{+0.57}_{-0.57}$  |
| $z = 3.5–10$             | 525               | 0.50$^{+0.06}_{-0.06}$  |
| $>10^{9.5}$              | 525               | 0.50$^{+0.06}_{-0.06}$  |
| $-4.0 < \beta < -1.75$   | 537               | $-0.24^{+0.09}_{-0.09}$ |
| $-1.75 < \beta < -1.00$  | 125               | 0.65$^{+0.54}_{-0.54}$  |
| $-1.00 < \beta < 0$      | 37                | 6.72$^{+0.47}_{-0.47}$  |

Notes.

a See Tables 9–10 from Appendix C for a more detailed presentation of the stack results summarized here.

b Both the bootstrap and formal uncertainties are quoted on the result (presented first and second, respectively).

### 3.4.2. Infrared Excess of a Function of Stellar Mass and UV-continuum Slope $\beta$

Having quantified the approximate relationship between the stellar mass and UV-continuum slope $\beta$ of galaxies at $z \sim 1.5–2.5$, we now move on to try to express the IRX as a bivariate function of the UV-continuum slope $\beta$ and the stellar mass $M$.

One reason for pursuing such a parameterization would be to take advantage of the greater information content present in both the measured UV-continuum slope $\beta$ and the inferred stellar mass of a galaxy. While the two parameters are clearly correlated (e.g., Section 3.4.1), they do provide us with independent information on sources and therefore should theoretically be able to improve our estimates of the IRX.

We use the following functional form:

$$\text{IRX}(\beta, M) = 1.7(10^{0.4(d\beta_{UV}/d\beta)+1})(M/M_\odot)^{3.5} \text{erg cm}^{-2} \text{s}^{-1} \mu\text{m}^{-1}$$

where $M(\beta)$ is as follows and gives the expected stellar mass for a given UV-continuum slope (as derived in the previous subsection):

$$M(\beta) = (10^{0.07M_\odot})(1.7 \times 10^{0.4(1.42)(\beta+2.3) - 1})^{1/0.92}.$$
I − 1.5 galaxies found with the ASPECS footprint with stellar masses less than $10^{9.25} M_\odot$, $10^{9.25}$ to $10^{9.75} M_\odot$, $10^{9.75}$ to $10^{10.25} M_\odot$, and $<10^{10.25} M_\odot$.) In the stacks, sources are weighted according to the inverse square of the noise. Note that the 18 individually detected sources from this analysis are not included in the presented stack results.

Figure 9. Stacked 1.2 mm continuum images ($12'' \times 12''$) for all candidate $z = 1.5$−3.5 galaxies falling in five different ranges of stellar mass ($>10^{9.25} M_\odot$, $10^{9.75}$ to $10^{10.25} M_\odot$, $10^{9.75}$ to $10^{10.25} M_\odot$, and $<10^{10.25} M_\odot$) and three different ranges of stellar mass at $z = 3.5$−10 ($>10^{9.25} M_\odot$, $10^{9.75}$ to $10^{10.25} M_\odot$, and $<10^{10.25} M_\odot$). The observed $\mu$Jy values for candidate $z = 1.5$−10 galaxies with stellar masses less than $10^{10.25} M_\odot$ is $-0.1 \pm 0.4 \mu$Jy beam$^{-1}$. This implies an average obscured SFR for these sources of $0.0 \pm 0.1 M_\odot$ yr$^{-1}$.

(Equation 8): Section 3.3.1, and (7) our derived IRX($\beta$, $M$) relation (Equation 13): Section 3.4.2. As one final predictor, we include a comparison against the flux density predicted taking the geometric mean of our derived $z = 1.5$−3.5 IRX−$\beta$ relation and our IRX−stellar mass relationship, i.e., (IRX$_\nu$IRX$^\alpha$)$^{1/2}$, and using Equations (9) and (8) while taking $dA_{\nu}/d\beta$, $\beta_{\text{int}}$, $M_\beta$, and $\alpha$ to be 1.81$^{+0.18}_{-0.14}$, 1.86$^{+0.14}_{-0.10}$, 10$^{9.15 \pm 0.16}$ $M_\odot$, and 0.97$^{+0.17}_{-0.17}$, respectively. This should provide for an alternate way of using both the UV-continuum slopes $\beta$ and stellar masses in estimating the IRX.

The observed fluxes are also explicitly compared against these many estimators in Figure 14. A quantification of the mean, median, and 1σ scatter in the logarithmic ratio of the predicted and measured 1.2mm flux densities is presented in Table 6, and it is clear there is substantial scatter between the observed and predicted flux densities. The scatter ranges from 0.65−0.81 dex, with the smallest dispersion found for the IRX($\beta$, $M$) and (IRX$_\nu$IRX$^\alpha$)$^{1/2}$ estimators, with only slight increases in the dispersion for the other relations. The IRX($\beta$, $M$) and (IRX$_\nu$IRX$^\alpha$)$^{1/2}$ estimators also provide the best predictions of the observed flux densities in the median.

As a separate means of evaluating the estimators, we compare the predicted 1.2mm flux densities from these estimators with the measured flux densities using both the detected sources in Table 6 and sources expected to be detected at $>\sigma$ averaging the IRX−$\beta$ and IRX−stellar mass relations derived here (Equations (9) and (8)), i.e., 70 sources in total. For each of these sources, we computed the difference between the measured and predicted flux for each source, i.e., $f_{\text{obs}}$ and $f_{\text{pred}}$, divided the result by the measurement error $e_{\text{obs}}$, and then determined the average as well as the upper and lower quartiles. For almost every estimator, the difference between the upper and lower quartiles is larger than the measurement error by $>5 \times$.

For each of the estimators, we also computed the differences between the measured and predicted flux densities for the same sources as the previous exercise, divided the result by the rms of the predicted flux densities and flux measurement uncertainties, and finally computed the upper and lower quartiles. This should give an approximate relative uncertainty on the flux density predictions. All of our estimators perform comparably well, with only modest differences between them. In summary, as with previous work (e.g., Meurer et al. 1999; Reddy et al. 2006), estimators of the IRX tend to be accurate in predicting the obscured SFRs or IR luminosities for the average source and tend to show at least $\sim$0.65 dex scatter for individual sources. Of those we consider, the different estimators for the IRX all perform comparably, with marginally better performance for the estimators that consider both mass $M$ and $\beta$, i.e., IRX($\beta$, $M$) and (IRX$_\nu$IRX$^\alpha$)$^{1/2}$, and the IRX$_{\text{M99}}$ estimator predicting the IRXs the least well.

4. Discussion

4.1. Previous Reported Continuum Detections

It is interesting to compare the present set of ALMA continuum detections to those that were previously reported over the HUDF by Aravena et al. (2016), Bouwens et al. (2016), and Dunlop et al. (2017). The reported detections and tentative detections by Aravena et al. (2016) and Bouwens et al. (2016) made use of the 1 arcmin$^2$ pilot for ASPECS, while the Dunlop et al. (2017) results were based on the 1.3mm ALMA continuum observations they obtained over a 4.5 arcmin$^2$ region within the HUDF/XDF.

Using the 1 arcmin$^2$ pilot observations for ASPECS, Aravena et al. (2016) and Bouwens et al. (2016) detected five $z > 1.5$ galaxies and reported tentative detections for three more $z > 1.5$ galaxies. Our new observations confirm all of our previously claimed detections at $>4\sigma$, making it clear that those detections were real. In addition, one of the tentatively detected sources from our pilot program, i.e., XDFFU-2370746171, shows a $>4\sigma$ detection (40 ± 11 $\mu$Jy beam$^{-1}$) in the new data, confirming that the reported tentative detection (34 ± 14 $\mu$Jy beam$^{-1}$) from our pilot was real.

The measured flux densities for the two other tentative detections from our pilot, i.e., XDFFU-2365446123 and XDFFU-2384246384, are $-27 \pm 17$ $\mu$Jy beam$^{-1}$ and $8 \pm 10$ $\mu$Jy beam$^{-1}$ versus our
measurements of $38 \pm 16 \mu$Jy beam$^{-1}$ and $36 \pm 14 \mu$Jy beam$^{-1}$, respectively, in the pilot for these sources. Combining the measurements, the flux is $7 \pm 12 \mu$Jy beam$^{-1}$ for XDFU-2365446123 and $17 \pm 8 \mu$Jy beam$^{-1}$ for XDFU-2384246384. While the new observations do not support the reality of either source, XDFU-2384246384 still shows a tentative $2\sigma$ detection in the continuum in the combined data set and thus may be real.

In the Dunlop et al. (2017) search, 16 dust-continuum ($>3.5\sigma$) detections are identified, 11 of which have an estimated redshift in excess of 1.5 and lie within the ASPECS footprint. 8 of these 11 sources are clearly confirmed with our ASPECS ALMA observations. For the 3 reported continuum detections from the Dunlop et al. (2017) which are not unambiguously confirmed by our ASPECS observations, we measure $-9 \pm 21 \mu$Jy (UDF9), $-45 \pm 31 \mu$Jy (UDF12), and $-3 \pm 9 \mu$Jy (UDF15).

4.2. Comparison with Previous Determinations of the Infrared Excess

It is interesting to compare the IRX–stellar mass and IRX–$\beta$ relations we derive with the many previous determinations in the literature. We focus on determinations at $z \sim 1.5$–3.5 since this is where our results are the most significant and where most of previous results have been obtained. In Figure 15, we compare the IRX–stellar mass relationship we find at $z \sim 1.5$–3.5 with what we obtained in our pilot study (Bouwens et al. 2016) and many other determinations in the literature (Heinis et al. 2014; Pannella et al. 2015; Álvarez-Márquez et al. 2016, 2019; Bourne et al. 2017; Fudamoto et al. 2017, 2020a; Koprowski et al. 2018; McLure et al. 2018; Reddy et al. 2018).

Overall, our new IRX–stellar mass results appear to be in agreement with previous results as presented, e.g., by Heinis et al. (2014), Pannella et al. (2015), Bourne et al. (2017), and McLure et al. (2018), or even as given by the consensus relation derived in our pilot study (shown with the gray line). Our best-fit IRX–stellar mass correlation is $\sim 0.2$–$0.3$ dex higher at $10^{10}$ $M_\odot$ than found in our earlier study (Bouwens et al. 2016) but consistent within the quoted uncertainties. Thanks to the larger number of dust-continuum detected sources in the current ASPECS study versus our pilot study (18 versus three $4\sigma$ detections), we are able to significantly improve our quantification of the IRX–stellar mass relation relative to our previous study.

The slope recovered for our new IRX–stellar mass relation, i.e., $0.97^{+0.17}_{-0.17}$, is very close to 1. We had previous adopted a value of unity in Bouwens et al. (2016) for the consensus relation (Equation (3)) based on the IRX–stellar mass results of Reddy et al. (2010), Whitaker et al. (2014), and Álvarez-Márquez et al. (2016). The IRX–stellar mass relation derived

![Figure 11](https://example.com/figure11.png)

**Figure 11.** (Left panel) Stacked constraints on the IRX in $z \sim 1.5$–3.5 galaxies vs. the UV-continuum slope $\beta$. These results are shown for higher- and lower-mass subsamples ($>10^{10} M_\odot$ and $<10^{10} M_\odot$) of $z \sim 1.5$–3.5 galaxies (red and green solid circles and downward arrows, respectively) and are obtained by stacking the ALMA 1.2 mm observations of individual sources over the ASPECS region. Upper limits and error bars on the stack results are $2\sigma$ and $1\sigma$, respectively. The smaller solid circles and downward arrows indicate $>3\sigma$ measurements and $3\sigma$ upper limits for individual sources. The black lines show the nominal IRX–$\beta$ relation for the Reddy (slightly steeper than Calzetti) and SMC dust laws (Equations (5) and (6)). The shaded red and light-green regions indicate the 68% confidence intervals on the IRX–$\beta$ relationship for sources with stellar masses of $>10^{10} M_\odot$ and $<10^{10} M_\odot$, respectively. Our results are consistent with the IR emission from high-mass ($>10^{10} M_\odot$) $z \sim 1.5$–3.5 galaxies exhibiting a Calzetti-like IRX–$\beta$ relation. The IRX–$\beta$ relation for lower-mass ($<10^{10} M_\odot$) galaxies is more consistent with an SMC-like dust relation. (Right panel) Stacked constraints on the IRX in $z = 3.5$–10 galaxies (for galaxies with $>10^{9.5} M_\odot$ in stellar mass) vs. $\beta$. The shaded red regions indicate the allowed range of IRX–$\beta$ relations alternatively fitting to the stacked detection at $\sim -0.8$ and $\sim 1.6$. Our $z = 3.5$–10 results are consistent with both a Reddy/Calzetti and an SMC relation, but with much larger uncertainties. While the fiducial results presented here from ASPECS assume an evolving dust temperature (Equation (1)), the dotted black open circle and upper limits show the results if the dust temperature is assumed to have a similar temperature at $z > 3$, i.e., $\sim 35$ K, as is the case at $z < 3$. 

In Figure 12, stacked 1.2 mm continuum images (12\arcsec × 12\arcsec) for \(z = 1.5–3.5\) and \(z = 3.5–10\) galaxies falling in different bins of UV-continuum slope \(\beta\). All sources that are individually detected at \(\geq 4\sigma\) are not included in the presented stack results. Only the most massive (>\(10^{7.5} M_\odot\)) sources are included in our \(z = 1.5–3.5\) and \(z = 3.5–10\) stacks, respectively. In the stacks, sources are weighted according to the inverse square of the noise.

Table 5

| Sample | Mass Range | \(dA_{UV}/d\beta\) | \(\beta_{\text{ext}}\) |
|--------|------------|---------------------|---------------------|
| Current Determinations | | | |
| \(z \sim 1.5–3.5\) | \(>10^{7.5} M_\odot\) | 1.81 ± 0.18 | 1.86 ± 0.14 |
| \(z \sim 1.5–3.5\) | \(<10^{7.5} M_\odot\) | 1.12 ± 0.31 | 1.86 (fixed) |
| \(z \sim 1.5–3.5\) | \(>10^{8.5} M_\odot\) | 1.48 ± 0.11 | 2.23 (fixed) |
| \(z \sim 1.5–3.5\) | \(<10^{8.5} M_\odot\) | 1.42 ± 0.09 | 2.30 (fixed) |
| Canonical IRX–\(\beta\) Relations | | | |
| Consensus: \(z \sim 0^e\) | 1.86 | −1.87 |
| Reddy et al. (2015): \(z \sim 2\) | 1.84 | −2.43 |
| Overzier et al. (2011): \(z \sim 5\) | 1.96 | −1.96 |
| Takeuchi et al. (2012): \(z \sim 0\) | 1.58 | −1.94 |
| Casey et al. (2014): \(z \sim 0\) | 2.04 | −1.64 |
| Meurer et al. (1999): \(z \sim 0\) | 1.99 | −2.23 |
| Dust Laws | | | |
| Calzetti | 1.97 | ... |
| SMC | ~1.10 | ... |

Note. 

\(^e\) Taking the median of the IRX–\(\beta\) relations derived by Overzier et al. (2011), Takeuchi et al. (2012), and Casey et al. (2014). See Appendix B.

by McLure et al. (2018) using the shallower ALMA observations over the HUDF (Dunlop et al. 2017) also find a slope (0.85 ± 0.05), very close to what we find here. At one other extreme, Fudamoto et al. (2020a) recover a much steeper slope (1.64 ± 0.10) for the IRX–stellar mass relation, similar to what we derive using PROSPECTOR for our stellar mass estimates (Appendix D). Meanwhile, earlier results obtained from an analysis of Herschel data by Pannella et al. (2015) find a much shallower IRX–stellar mass relation, with a slope of ~1.04, clearly shallower than what we find here (also see results by Álvarez-Márquez et al. 2019). Given the current strong constraints on the obscured SFR at low masses (<\(10^{7.25} M_\odot\)) and the challenge that source confusion presents for the lowest mass sources with Herschel, it seems likely that the slope of the IRX is approximately unity or steeper, as essentially all analyses relying on ALMA data have found.

The IRX–stellar mass results we obtain at \(z \sim 3.5–10\) can be compared with results obtained using a small sample of bright \(z \sim 5–6\) galaxies from Capak et al. (2015) and Willott et al. (2015) and assuming the dust temperature evolution given in Equation (1). Also included in this comparison are the new ALPINE results from Fudamoto et al. (2020b), both as quoted in the original study (solid colored points) and adopting the fiducial dust temperature evolution adopted here (Equation 1). This comparison is presented in Figure 16. Our own results appear to be more consistent with the consensus IRX–\(M_\star\) relationship we had derived in our pilot study (Bouwens et al. 2016) and now derived here as \(z \sim 1.5–3.5\). While this suggests that the IRX–stellar mass relation may extend to \(z \sim 5–6\) with little or no evolution, the ASPECS field only contains a few bright, massive sources to probe this well. Additionally, this inference depends critically on the dust temperature being relatively high, i.e., ~50 K, at \(z \sim 4–6\). If the temperature is instead ~41 K as Fudamoto et al. (2020b) adopt in their analysis, clearly the IRX–stellar mass relation at \(z > 3.5\) is lower than what is found at \(z \sim 1.5–3.5\).

In Figure 17, we compare the IRX–\(\beta\) relationship we derive for higher-mass, \(z \sim 1.5–3.5\) galaxies with the results obtained in our pilot study (Bouwens et al. 2016) as well as a wide variety of different determinations in the literature (Heinis et al. 2013; Álvarez-Márquez et al. 2016, 2019; Bourne et al. 2017; Fudamoto et al. 2017, 2020a; Koprowski et al. 2018; McLure et al. 2018; Reddy et al. 2018). Similar to what we found for the IRX–stellar mass relation, the larger number of dust-continuum detections found here (versus from the smaller-area ASPECS pilot) results in the recovery of a steeper IRX–\(\beta\) relation than in our pilot, i.e., 1.48 ± 0.09 versus 1.26 ± 0.26 when...

---

Bouwens et al.
Figure 14. Comparison of the predicted and measured flux densities of $z \gtrsim 1.5$ galaxies at 1.2 mm within the ASPECS footprint. The predicted flux densities (shown with the red solid circles) are based on the UV magnitudes observed and the IRX–stellar mass, and IRX($\beta$, M) relations we derive here (Equations (9), (8), (13); Sections 3.3.2, 3.3.1, 3.4.2). The open blue circles in the left panel compare the predicted and measured flux densities based on an IRX–SMC relationship (Equation (6)). The red downward pointing arrows correspond to $3\sigma$ upper limits.

Figure 15. Comparison of the present determinations of the IRX–stellar mass relation at $z \sim 1.5$–3.5 with many previous determinations in the literature, including from the pilot study to ASPECS (Bouwens et al. 2016; open red circles), McLure et al. (2018; solid black circles), Reddy et al. (2018; solid green circles), Pannella et al. (2015; solid magenta circles), Fudamoto et al. (2017; solid light-red circles), Koprowski et al. (2018; open black circles), Fudamoto et al. (2020a; solid light-green circles), Bourne et al. (2017; solid yellow circles), Álvarez-Márquez et al. (2016; solid blue circles), Álvarez-Márquez et al. (2019; open blue circles), and Heinis et al. (2014) at both $z \sim 2$ (solid gray circles) and $z \sim 3$ (solid violet circles). The solid black line gives the IRX vs. stellar mass trend Whitaker et al. (2017) derive for their results over the full range $z \sim 0$–3, while the shaded gray region gives the consensus IRX–stellar mass relation we derived for select literature results in our pilot study. The light-red shaded line is a fit to our IRX stack results vs. stellar mass. Our new results are in agreement with previous work over the entire mass range well probed by this study ($10^9$–$10^{11} M_\odot$).

fixing $\beta_{\text{int}} = -2.23$. The only apparently significant difference occurs for our determination at $-1.3$ where the limit from our pilot program was $1.31^{+0.67}_{-0.54} \pm 0.72$ (at $\beta \sim -1.4$) and where our new measurement is $6.54^{+4.38}_{-4.97} \pm 0.28$ (at $\beta \sim -1.2$). This difference results both from the larger number of dust-detected sources in the four times larger area probed by ASPECS (versus our pilot) and from our change of the $\beta$ binning scheme to exploit the larger number of sources to improve our leverage for constraining the IRX–$\beta$ relation.

Relative to various determinations from the literature, the most significant differences occur for the bluest values of $\beta$, i.e., $\beta \sim -1.8$, where our own determination of the IRX is some 0.2–1.0 dex lower than the determinations of Reddy et al. (2018), Fudamoto et al. (2017), Bourne et al. (2017), and McLure et al. (2018). It seems likely that the differences here are due to the presence of blue, IR-luminous sources in many previous selections. While blue, IR-luminous galaxies are known to exist (e.g., Reddy et al. 2006; Casey et al. 2014), especially at high IR luminosities ($>10^{12} L_\odot$) where there is less connection between the UV and IR morphologies in galaxies, these sources are not sufficiently common to be well sampled by the $\sim 2.5 \times 10^6$ comoving Mpc$^3$ volume probed by ASPECS at $z = 1.5$–3.5.

Otherwise, our IRX–$\beta$ results are broadly in agreement with the results of Reddy et al. (2018), Álvarez-Márquez et al. (2016), and Heinis et al. (2013). For redder values of $\beta$, our IRX–$\beta$ results are lower than the results of McLure et al. (2018); Fudamoto et al. (2017), Bourne et al. (2017), and Fudamoto et al. (2020a) by $\sim 0.4$ dex. We expect that some fraction of these differences, i.e., 0.3 dex, could result from different calibrations used to derive the IR luminosities and obscured SFRs from the measured ALMA fluxes (e.g., Murphy et al. 2011 versus Whitaker et al. 2017).

4.3. Dust Corrections for $z \gtrsim 3$ Samples

The purpose of this section is to take advantage of the results of our analyses from the previous subsections to derive dust corrections that we can apply to the general star-forming galaxy population at $z \gtrsim 3.5$. 

We will focus on deriving these corrections as a function of the UV luminosity of galaxies and derive a distribution of dust corrections that make up each UV luminosity bin. To ensure a consistent dust temperature evolution model, the dust correction we compute would be approximately half as large. As in Bouwens et al. (2016), we apply the dust corrections we derive in the previous subsection to the UV luminosity densities of Bouwens et al. (2015) identified at $z \sim 3$, 4, 5, 6, 7, 8, and 10 over the CANDELS GOODS-North and GOODS-South.

Each of the sources over the CANDELS GOODS-North and GOODS-South fields has sensitive HST optical/ACS and WFC3/IR photometry available to derive UV-continuum slopes for each source in these samples. Another valuable aspect of sources in these fields is the deep Spitzer/IRAC observations that exist from the 200 hr GREATS program (M. Stefanon et al. 2020, in preparation) to provide rest-optical photometry for $z \sim 4–8$ galaxies and thus to estimate stellar masses. HST and Spitzer/IRAC photometry is performed on sources in these fields in a similar way to that described in Section 2.2, and UV-continuum slopes $\beta$ and stellar masses are estimated using the FAST stellar population fitting code as described in Section 2.5.

In deriving dust corrections for each bin in UV luminosity, we make use of the stellar masses and UV-continuum slopes $\beta$ derived for our large CANDELS samples and utilize the new relation in Equation (13) we derived in Section 3.4.2 for the IRX expressed as a function of both $\beta$ and stellar mass $M_\star$. To ensure that our extinction estimates are not overly impacted by noise in the photometry scattering lower-mass sources to red $\beta$ measurements, we force the IRXs of sources with stellar masses less than $10^9 M_\odot$ to be zero, consistent with our derived observational constraints.
This relationship assumes a constant SFR for 100 Myr. We also apply these dust corrections to the Reddy & Steidel (2009) and McLure et al. (2013) LF results. Our quantitative results for the corrected and uncorrected SFR densities at $z \sim 3$–10 are presented in Table 8.

In computing the SFR density, we must account not only for the impact of dust extinction on the UV luminosities themselves but also for the more massive, far-IR bright sources where standard dust corrections are not effective or which are sufficiently faint in the UV to be entirely missed in standard LBG searches (e.g., Reddy et al. 2006, 2008; Swinbank et al. 2014; Casey et al. 2018; Williams et al. 2019; Dudzevičiūtė et al. 2020). Such sources are known to contribute a substantial fraction of the SFR density at $z \sim 0$–3 (Hughes et al. 1998; Blain et al. 1999; Lilly et al. 1999; Chapman et al. 2005; Karim et al. 2011; Barger et al. 2012; Magnelli et al. 2013; Madau & Dickinson 2014; Swinbank et al. 2014; Wang et al. 2019; Dudzevičiūtė et al. 2020). Perhaps the best way to account for these galaxies (proposed earlier by Reddy et al. 2008) is to simply include them based on dedicated searches for these sources in the IR.

We consider the results of Magnelli et al. (2013) at $z \sim 0$–2 (which build on the results of Caputi et al. 2007 and Magnelli et al. 2009, 2011), the Franco et al. (2020a) results at $z \sim 2$–5 from a 69 arcmin$^2$ survey area, the Yamaguchi et al. (2019) results at $z \sim 3$–5 from the 26 arcmin$^2$ ASAGAO survey area, and the Williams et al. (2019) serendipitous discovery of a probable dusty star formation source at $z \sim 5$. We compute the SFR density contribution from ultraluminous IR-type galaxies (ULIRGs) at $z \sim 2.5$ from the ASPECS volume by converting the measured ALMA fluxes from detected sources in their survey area to SFRs assuming 100% of the energy comes from star formation, binning the contributions by the derived redshifts for the sources, and then dividing by the cosmic volume within a 4.2 arcmin$^2$ survey area, finding $0.036 \pm 0.022 M_\odot$ yr$^{-1}$. We use a similar approach to derive the SFR density contribution from ULIRGs at $z \sim 2$–5 from the 69 arcmin$^2$ Franco et al. (2020a) probe, but given the limited depth of this probe, we treat this derived contribution as a lower limit. The Franco et al. (2020a) probe builds on the earlier Franco et al. (2018) study using deeper search results presented in Franco et al. (2020b).

Additionally, we consider the integrated SFR density derived from MAGPHYS fits to the $\sim 1$ deg$^2$ AS2UDS sample by Dudzevičiūtė et al. (2020), who corrected for incompleteness using the number counts from Geach et al. (2017) and extrapolated from the observed 870 $\mu$m flux limit of 3.6 mJy for the SCUBA-2 survey to 1 mJy using the slope of the number counts from Hatsukade et al. (2018). See Section 5.4 and Figure 15 from Dudzevičiūtė et al. (2020) for further details. The uncertainties on the values were calculated by resampling the SFR and redshift probability distributions of each source. The approximate survey volume for the AS2UDS results is approximately $7 \times 10^7$ Mpc$^3$ and so is likely to be much more representative than smaller volume studies.

Finally, we also estimate the SFR density from ULIRG-type sources by assuming that the star-forming main sequence results of Speagle et al. (2014) apply to the wide-area $z \sim 1$–5 mass functions of Ilbert et al. (2013) and $z \sim 3$–6 mass functions of Davidzon et al. (2017). Encouragingly, the estimated SFR contribution provided by ULIRG-type galaxies using the observed mass functions appears to be plausibly consistent with that derived from constraints available from direct searches for ULIRG-type sources at $z = 2$–4 and $\sim 0.2$ dex higher at $z = 4$–6.

A summary of the inferred SFR density for all the aforementioned ULIRG probes is presented in Figure 18. As our fiducial estimate of the obscured SFR density from ULIRGs, we adopt the Magnelli et al. (2013) constraints at $z \sim 2$, our mass-function-derived estimate at $z \sim 2.75$, the AS2UDS estimates (Dudzevičiūtė et al. 2020) at $z = 3.4$–6, and the Wang et al. (2019) at $z > 6$. We have indicated fiducial obscured SFR densities in Figure 18 with the hatched red area. This fiducial model is most consistent with the dust-poor model from Casey et al. (2018).

We combine these SFR densities with those we derived by correcting the UV LFs at $z = 3$–10 to present our best estimates for the SFR density at $z = 3$–10 in Table 8 and Figure 19, together with a few previous estimates (Schimovich et al. 2005; Reddy & Steidel 2009; McLure et al. 2013) in Figure 19. It is interesting to compare the contribution that unobscured and obscured star formation makes to the total SFR density of the universe. Figure 20 shows such a breakdown of the SFR density. The obscured SFR density shown at $z < 2$ is from the Magnelli et al. (2009, 2011, 2013), while at $z \sim 2$–3, the obscured SFR density shown is the sum of the SFR density from AS2UDS (Dudzevičiūtė et al. 2020) and from Reddy & Steidel (2009). The contribution to the SFR density from ULIRGs is presented for context. From the presented breakdown, we can see that star formation is mostly unobscured at $z > 5$, mostly obscured at $z < 5$, and $z \sim 5$ marks the approximate transition redshift between the two regimes. Previously, Bouwens et al. (2009), Bouwens et al. (2016), and Dunlop et al. (2017) found that the approximate transition point between the two regimes was $z \sim 4$.

### 4.5. Star Formation Rate Density in the ASPECS Volume

Finally, before closing the discussion we provide in this paper on the SFR density, it is interesting to try to estimate the SFR density within the ASPECS HUDF/XDF volume itself. Given the limited volume probed by ASPECS and the impact of large-scale structure, this is an interesting issue to examine to

### Table 7

Estimated Dust Corrections to Apply to the UV Luminosity Density Results Integrated to Various Limiting Luminosities

| Sample | log$_{10}$ Dust Correction $(>-0.05 L^*_{f,\nu})^b$ | log$_{10}$ Dust Correction $(>-0.03 L^*_{f,\nu})^b$ |
|--------|---------------------------------|---------------------------------|
| $z \sim 3$ | 0.37$^a$ | 0.34$^a$ |
| $z \sim 4$ | 0.33 | 0.31 |
| $z \sim 5$ | 0.30 | 0.27 |
| $z \sim 6$ | 0.20 | 0.17 |
| $z \sim 7$ | 0.09 | 0.07 |
| $z \sim 8$ | 0.07 | 0.06 |

**Notes.**

$^a$ For uniquely the $z \sim 3$ sample, we make use of the finding by, e.g., Reddy & Steidel (2004) and Reddy et al. (2010) that the average IRX for galaxies brighter than 25.5 mag at $z \sim 3$ is a factor of $\sim 5$.

$^b$ The specified limits $0.05 L^*_{f,\nu}$ and $0.03 L^*_{f,\nu}$ correspond to faint-end limits of $\sim 17.7$ and $\sim 17.0$, respectively, which is the limiting luminosity to which $z \sim 7$ and $z \sim 10$ galaxies can be found in current probes (Schenker et al. 2013; McLure et al. 2013; Ellis et al. 2013; Oesch et al. 2013; Bouwens et al. 2015).
help determine the extent to which conclusions drawn from the HUDF volume are applicable to much larger cosmic (∼10^8 comoving Mpc^3) volumes of the universe (where the impact of large-scale structure is less).

To estimate the approximate SFR density within the ASPECS volume, we rederive the UV LF at z ∼ 2, z ∼ 3, z ∼ 4, z ∼ 5, z ∼ 6, z ∼ 7, z ∼ 8, and z ∼ 10 but only using sources in the ASPECS/HUDF/XDF volume. For simplicity, in deriving this LF, we fix the faint-end slope α and characteristic luminosity M^* to that derived from Bouwens et al. (2015) and R. Bouwens et al. (2020, in preparation) at these same redshifts and fit for the normalization φ^*.

Table 8

| Lyman | log_{10} L (erg s^{-1} Hz^{-1} Mpc^{-3}) | Dust Correction (dex) | log_{10} SFR Density (M_☉ yr^{-1} Mpc^{-3}) |

| I | 10.4 | 24.62 ± 0.36 | 0.00 | −3.28 ± 0.36 | −3.28 ± 0.36 | −3.28 ± 0.36 |

Notes.

a Integrated down to 0.03 L^*_{z=3}. Based upon LF parameters in Table 2, Section 6, of Bouwens et al. (2015). The SFR density estimates assume ≥100 Myr constant SFR and a Chabrier IMF (e.g., Madau & Dickinson 2014). Conversion to a Salpeter (1955) IMF would result in a factor of ∼1.6 (0.2 dex) increase in the SFR density estimates given here.

b The contribution indicated here is our fiducial estimate from far-IR bright, ULIRG-like (∼10^{12} L_☉) galaxies (see Figure 18). The SFR density contribution for the far-IR bright population tends to be either missed completely due to these sources not being selected in Lyman-break galaxy probes (e.g., Simpson et al. 2014) or significantly underestimated due to the IR luminosities underestimated based on their UV properties (e.g., Reddy & Steidel 2009).
Here we make use of sensitive observations we have obtained from the ALMA large program ASPECS of far-IR continuum light for a large sample of $z = 1.5$–10 galaxies located over the HUDF. ASPECS probes with great sensitivity ($9.3 \, \mu \text{Jy beam}^{-1}$: $1 \sigma$) the 1.2 mm far-IR continuum of $z \geq 2$ galaxies and extends over a 4.2 arcmin$^2$ region using 90 hr of band 6 observations in total. With these observations, we probe dust-enshrouded star formation to $7$–$28 \, M_{\odot}$ yr$^{-1}$ ($4 \sigma$) from 1362 robust $z = 1.5$–10, UV-selected galaxies located over the ASPECS footprint. These $z = 1.5$–10 sources were either drawn from the literature (Bouwens et al. 2015) or selected specifically for this study by applying standard color selection criteria to the deep WFC3/UVIS observations over the HUDF from the UVUDF program (Teplitz et al. 2013; Rafelski et al. 2015).

Eighteen of the $z > 1.5$ galaxies within our ASPECS footprint are detected at $>4 \sigma$ in our 1.2 mm continuum observations. Twelve of the 18 $>4 \sigma$ detections were previously identified as part of the ASPECS pilot program (Aravena et al. 2016; Bouwens et al. 2016) or the Dunlop et al. (2017) program. Six of the reported continuum detections are new discoveries from the ASPECS large program (see Aravena et al. 2020; González-López et al. 2020).

The observed number of continuum detections is in agreement with the predictions obtained by applying a consensus low-redshift IRX–$\beta$ relationship derived here (Appendix B) to the highest-mass $z = 1.5$–10 galaxies found over ASPECS and suggests a likely sample of 28 continuum detections, while only 16 continuum detections are predicted if only sources with stellar masses in excess of $10^{9.5} \, M_{\odot}$ are considered. This consensus IRX–$\beta$ relationship is constructed by combining the IRX–$\beta$ relations derived in Overzier et al. (2011), Takeuchi et al. (2012), and Casey et al. (2014).

In agreement with previous studies, we find that the fraction of detected galaxies in our samples increases sharply with increasing stellar mass, with the detection fraction rising from $0\%$ at $10^{9.0} \, M_{\odot}$ to $85\%$ at $10^{10} \, M_{\odot}$. For sources probed to a sensitivity of $<20 \, \mu \text{Jy beam}^{-1}$, Interestingly, at low stellar masses, i.e., $<10^{9.5} \, M_{\odot}$, stacking all 1253 sources in our catalogs over the ASPECS footprint, we recover an average 1.2mm flux density of $-0.1 \pm 0.4 \, \mu \text{Jy beam}^{-1}$, implying that the obscured SFR of lower-mass galaxies is essentially zero, i.e., $0.0 \pm 0.1 \, M_{\odot}$ yr$^{-1}$ (converting the flux density constraint to SFR at $z \sim 4$).

The IRX ($\text{IRX} = \text{L}_{\text{IR}}/\text{L}_{\text{UV}}$) of galaxies in our $z = 1.5$–3.5 sample shows a strong correlation with the estimated stellar mass $M$, with a best-fit relation $\text{IRX} = (M/10^{10})^{1.18} \, \text{erg s}^{-1} \, \text{Hz}^{-1}$. Both the recovered normalization and slope of this relation is in agreement with previous work. The IRX of galaxies in our $z = 3.5$–10 sample seems to show approximately the same relationship with stellar mass. Unfortunately, there are an insufficient number of high-mass star-forming galaxies within the ASPECS volume to constrain the relation.

However, we do note that, for our particular sample of galaxies, the IRX versus stellar mass relation we derive does show some dependence on which stellar population we use to estimate stellar masses. If we instead use PROSPECTOR (Leja et al. 2017) stellar population model to estimate masses for sources in our sample instead of FAST (Kriek et al. 2009), we derive a steeper IRX–stellar mass relationship.

Figure 19. Updated determinations of the derived SFR (left axis) and UV luminosity (right axis) densities vs. redshift (Section 4.4). The left axis gives the SFR densities we would infer from the measured luminosity densities, assuming the Madau et al. (1998) conversion factor relevant for star-forming galaxies with ages of $\geq 10^8$ yr (see also Kennicutt 1998). The right axis gives the UV luminosities we infer integrating the present and published LFs to a faint-end limit of $-17$ mag ($0.03 \, L_{\odot}$; $z > 8$) –which is the approximate limit we can probe to $z > 8$ in our deepest data set. The upper and lower set of points (red and blue circles, respectively) and shaded regions show the SFR and UV luminosity densities corrected and uncorrected for the effects of dust extinction.

The dust correction we utilize relies on the bivariate IRX($\beta$, $M_*$) relation derived here (Equation (13)) for galaxies with solar masses $>10^8 \, M_{\odot}$ and otherwise we take the correction to be zero. The dust-corrected SFR density we quote includes the contribution of far-IR luminous ($>10^{12} \, L_{\odot}$) galaxies, as indicated by the fiducial SFR density in Figure 18. The dark red shaded region shows the implied SFR densities to $z < 2$ from dust-obscured and IR-luminous sources (Magnelli et al. 2013). Also shown are the SFR densities at $z \sim 2$ and $z \sim 3$ from Reddy & Steidel (2009; green squares), at $z \sim 0$–2 from Schiminovich et al. (2005; black hexagons), at $z \sim 7$–9 from McLure et al. (2013) and Ellis et al. (2013); cyan solid circles, and $z \sim 9$–11 from Cluster Lensing and Supernovae survey with Hubble (CLASH; Zheng et al. 2012; Coe et al. 2013; Oschel et al. 2014b; light blue circles). The $z \sim 9$–11 constraints on the UV luminosity density have been adjusted upwards to a limiting magnitude of $-17.0$ mag assuming a faint-end slope $\alpha$ of $-2.0$ (consistent with our constraints on $\alpha$ at both $z \sim 7$ and $z \sim 8$).

relative normalization we derive for the UV LFs over the ASPECS areas relative to the cosmic average, i.e., $\phi^{\text{ASPECS}}_{\text{SFR}}/\phi^\ast$ is 1.17, 0.85, 0.68, 0.74, 1.10, 0.95, 0.98, 1.29, and 0.50 at $z \sim 2$, $z \sim 3$, $z \sim 4$, $z \sim 5$, $z \sim 6$, $z \sim 7$, $z \sim 8$, $z \sim 9$, and $z \sim 10$, respectively. The rms logarithmic scatter in these normalizations are $0.12$ dex, i.e., fluctuations of $32\%$ ($0.12$ dex) in the volume density of galaxies in a given redshift interval of the HUDF relative to the cosmic average. $32\%$ is fairly similar to the expected variations one would expect for sources with a volume density of $\sim 1 \times 10^{-3} \, \text{Mpc}^{-3}$ inside a $2\prime \times 2\prime \times \Delta z \sim 1$ volume. Figure 21 illustrates how the SFR density we infer from the HUDF might compare with the cosmic average, if we assume that we can apply the LF normalization factors just derived to the SFR density as a whole.

To assess the impact of large-scale structure on the present results and other results from ASPECS, it is relevant to compare the observed $0.12$ dex scatter with that expected from the relatively small number of dust-detected and CO-detected sources over ASPECS. In cases where the number of sources per unit redshift is in the range $10$–15, i.e., similar to the number of dust-detected and CO-detected sources in ASPECS (e.g., Boogaard et al. 2019; González-López et al. 2020), the scatter expected from small number statistics will be comparable to that seen in terms of large-scale structure. This suggests that any conclusions drawn from the HUDF ASPECS volume should be applicable to much larger cosmic ($\sim 10^6$ comoving Mpc$^3$) volumes, with a relatively limited impact from large-scale structure.
The SFR density of the universe is predominantly unobscured at $(z > 2)$, and assuming that the same corrections for dust apply to both the relative normalization of the UV LF over the ASPECS area to that derived over much wider areas and assuming that the same corrections for dust (and a missing ULIRG contribution) apply to both.

The IRX–β relation we recover for higher-mass $>10^{9.5} M_{\odot}$ galaxies is most consistent with a Calzetti-like IRX–β relation (here represented with the Reddy et al. 2015 dust curve). The relation we derive is somewhat steeper than we previously derived (Bouwens et al. 2016), but is nevertheless consistent. Our new IRX–β relation is similar to that derived by many previous teams (Reddy et al. 2018; Álvarez-Márquez et al. 2016; Heinis et al. 2013), but lower than some others (McLure et al. 2018), especially at blue β’s (i.e., $\beta \sim -1.8$). For lower-mass $z \sim 1.5$–3.5 galaxies, the IRX–β relation we derive is most consistent with an SMC-like relation.

Using stellar mass and β measurements for $z \sim 2$ galaxies over CANDELS, we derive the following new empirical relation between β and stellar mass:

$$M(\beta) = (10^{0.07} M_{\odot}) (1.7 \times 10^{0.4(1.42)^{2}+2.3}) - 1.$$  

We then use this correlation to show that our IRX–β and IRX–stellar mass relations are closely connected (see also McLure et al. 2018; Carvajal et al. 2020). We then use these constraints to express the IRX as the following bivariate function of β and stellar mass:

$$\text{IRX}(\beta, M) = 1.7(10^{0.4 d_{\text{UV}}/d\beta}(\beta+2.3) - 1)(M/M(\beta))^\alpha.$$  

The best-fit values we derive for $d_{\text{UV}}/d\beta$ and α are $1.48 \pm 0.10$ and $0.67 \pm 0.06$, respectively, using our ASPECS measurements.

We quantify the stacked constraints on the IRX in $z > 3.5$ galaxies as a function of stellar mass and β results and recover results at $z > 3.5$ consistent with what we find at $z = 1.5$–3.5 if we assume a significant evolution in dust temperature with redshift (e.g., as found by Schreiber et al. 2018 or using our Equation (1)). If the dust temperature of $z \sim 3.5$–10 galaxies instead remains fixed at 35 K (e.g., Dudzevičiūtė et al. 2020), we recover IRXs at $z > 3.5$ that are 0.4 dex lower than at $z = 1.5$–3.5.

Finally, we make use of our improved constraints on the dependence of the IRX on β and stellar mass to provide new estimates of the dust corrections for the general star-forming galaxy population at $z \geq 4$. We determine these dust corrections as a function of UV luminosity and use the measured UV-continuum slopes, stellar masses, and UV luminosities for large numbers of $z \sim 4, 5, 6, 7,$ and 8 galaxies identified over the CANDELS GOODS-South and GOODS-North fields to compute these corrections.

We then leverage these new dust corrections and the UV LF determinations from Bouwens et al. (2015) to provide updated
estimates of the SFR density at \( z = 4-10 \). We explicitly subdivide these SFR density estimates into the obscured and unobscured contributions and show that the transition point from where the SFR density transitions from being primarily unobscured to obscured is \( z \sim 5 \). Previously, Bouwens et al. (2009, 2016) and Dunlop et al. (2017) found that the approximate transition point between the two regimes was \( z \sim 4 \).

In the future, we can look forward to further significant progress in our understanding of obscured star formation at high redshift from targeting large numbers of moderate to high-mass galaxies at \( z > 3.5 \) as is being done with the ALPINE program (le Fevre et al. 2019). Improvements in our constraints on the dust temperatures of \( z > 3 \) galaxies from shorter and longer wavelength observations will be valuable in computing more accurate IR luminosities of individual sources. Also important will be the discovery of larger, statistical samples of IR-luminous, dusty star-forming galaxies (e.g., Dudzevičiūtė et al. 2020) to achieve a more complete census of the total SFR density at \( z > 3 \). Finally, at the extreme low-luminosity end, further progress will be made in searching for obscured star formation in individual low-luminosity sources through the ALMA Lensing Cluster survey large program (2018.1.00035. L, Pf: Kohno).

We thank Matthieu Béthermin for helpful discussions. This paper benefited greatly from a helpful report from an anonymous referee. This paper makes use of the ALMA data from the program 2016.1.00324.L. ALMA is a partnership of ESO (representing its member states), NSF (USA) and NINS (Japan), together with NRC (Canada), NSC and ASIAA (Taiwan), and KASI (Republic of Korea), in cooperation with the Republic of Chile. The Joint ALMA Observatory is operated by ESO, AUI/NRAO, and NAOJ. R.J.B., M.S., and T.N. acknowledge support from NWO TOP grant TOP1.16.057. J.G.-L. acknowledges partial support from ALMA-CONICYT project 31160033. I.R.S. acknowledges support from STFC (ST/P000541/1). F.W. and M.N. acknowledge support from ERC Advanced Grant 740246 (Cosmic Gas). U.D. acknowledges the support of STFC studentship (ST/R504725/1). D.R. acknowledges support from the National Science Foundation under grant numbers AST-1614213 and AST-1910107 and from the Alexander von Humboldt Foundation through a Humboldt Research Fellowship for Experienced Researchers. Appendix A
Comparison of Our Fiducial Stellar Mass Estimates with Those from MAGPHYS and PROSPECTOR

In this appendix, we compare the fiducial stellar masses we derive for sources in our study using FAST (\( z > 2.5 \)) with those derived from the MAGPHYS software (da Cunha et al. 2008) which is used in many of the other ASPECS analyses (e.g., Magnelli et al. 2020). The stellar masses we estimate are in agreement with our fiducial results, with the median and mean stellar mass derived by MAGPHYS being 0.07 dex and 0.36 dex higher, respectively, with a median absolute difference between the two mass estimates of 0.38 dex. This is consistent with their being no major systematic biases in the results from the present study—which rely on FAST-estimated masses—relative to other papers in the ASPECS series—where the reliance is on MAGPHYS-estimated masses.

We also compared our stellar mass estimates with those we derived from the PROSPECTOR code (Leja et al. 2017) to \( z < 2.5 \) where Leja et al. (2019) publish stellar mass results based on the Skelton et al. (2014) photometry. PROSPECTOR has many advantages for deriving robust mass estimates for sources given its flexibility in accounting for a wide variety of different star formation histories, dust extinction and reradiation, dust extinction curves, stellar metallicities, and nebular emission. The median and mean stellar mass found with PROSPECTOR from the Leja et al. (2019) compilation is 0.12 dex and 0.19 dex higher, respectively, than what we find from FAST for sources over the ASPECS HUDF area. The rms difference is 0.28 dex.

Appendix B
Consensus \( z \sim 0 \) IRX–\( \beta \) Relationship

Results from the \( z \sim 0 \) universe provide us with an important baseline for interpreting dust-continuum results in the \( z > 1.5 \) universe. This is especially the case given the limited evolution in the relationship between the IRX and UV-continuum slope \( \beta \) from \( z \sim 2 \) to \( z \sim 0 \) (Reddy et al. 2006; McLure et al. 2018) and also limited evolution in the IRX–stellar mass relationship (e.g., Pannella et al. 2009; Whitaker et al. 2017).

The conventional \( z \sim 0 \) reference point has been the Meurer et al. (1999) relation. However, it is now clear based on a large amount of work that the actual \( z \sim 0 \) relation should shift both to redder \( \beta \)'s and lower IRXs (Overzier et al. 2011; Takeuchi et al. 2012; Casey et al. 2014). Instead of debating the merits of three recent determinations of the IRX–\( \beta \) relationship at \( z \sim 0 \) by Overzier et al. (2011), Takeuchi et al. (2012), and Casey et al. (2014), perhaps the easiest approach is just to fit the mean of the parameters derived in these studies, and use that as our relation. The means we derive for the intrinsic (unreddened) UV-continuum slope of stellar populations, i.e., \( \beta_{\text{int}} \), and \( \Delta \log_{10} \frac{BC_{\text{dust}}}{BC_{\text{dust}}} \) (with no weighting) are \(-1.85 \) and \(-1.86 \), respectively, such that \( A_{\text{FUV}} = 1.86(\beta + 1.85) \) for \( \beta < -1.85 \).

Following Meurer et al. (1999), the expression for the IRX (\( L_{IR}/L_{UV} \)) is

\[
\log_{10} L_{IR} = \log_{10}(10^{0.4A_{\text{FUV}}} - 1) + \log_{10} \frac{BC_{\text{FUV},*}}{BC_{\text{dust}}}. \tag{B1}
\]

In this treatment, \( BC_{\text{FUV},*} \) and \( BC_{\text{dust}} \) are the bolometric corrections from the \( L_{UV} \) and \( L_{IR} \) luminosities to the total luminosities in the UV and IR. Taking \( L_{UV} \) to be equal to \( L_{F} \) evaluated at 1600 Å, typical estimates for \( BC_{\text{FUV},*} \) have been in the range of \( 1.66–1.71 \) (Meurer et al. 1999), and we will take \( BC_{\text{FUV},*} \) to be equal to 1.7. If we also treat \( L_{IR} \) as the total IR luminosity (8–1000 μm), we see that \( BC_{\text{dust}} \) is approximately equal to 1.

\(^{23}\) This shift in the \( z \sim 0 \) relation from Meurer et al. (1999) is a result of the fact that the effective aperture of the IUE observations were too small to probe the full UV luminosities of sources in the Meurer et al. (1999) sample.
Table 9
Stacked Results: IRX versus Stellar Mass

| Mass (M) | Number of Sources | log(M/M_☉) | Measured Flux (μJy) | Predicted f_{1.2mm} | Flux Mass (μJy) | Measured IRX | Measured f_{1.2mm}/f_{UV} |
|---------|-----------------|------------|---------------------|---------------------|----------------|--------------|-------------------------|
| >10^{10.75}M_☉ | 5 | 10.9 | 0.3 | 337±0.03^6 | 603 | 41.70±0.18 | 0.00 | 645±0.14 |
| 10^{10.25}M_☉<10^{10.75}M_☉ | 6 | 10.5 | 0.0 | 190±0.00 | 214 | 21.88±0.00 | ±0.00 | 0.00±0.00 |
| 10^{10.25}M_☉<10^{10.75}M_☉ (ind. <4σ) | 0 | 0.0 | 0.0 | 0.00±0.00 | 0 | 0.00±0.00 | ±0.00 | 0.00±0.00 |
| 10^{10.75}M_☉<10^{10.25}M_☉ | 11 | 9.9 | -1.0 | 166±0.13 | 78 | 13.56±0.02 | ±0.00 | 448±0.02 |
| 10^{10.75}M_☉<10^{10.25}M_☉ (ind. <4σ) | 9 | 9.9 | -0.9 | 21±0.00 | 51 | 2.47±0.00 | ±0.00 | 31±0.00 |
| 10^{10.25}M_☉<10^{10.75}M_☉ | 33 | 9.5 | -1.4 | 26±0.00 | 39 | 1.81±0.00 | ±0.00 | 30±0.00 |

| <10^{7.75}M_☉ | 467 | 8.2 | -1.9 | 0.6±0.00 | 0 | 0.59±0.00 | ±0.00 | 0±0.00 |

Notes.

- This column presents stack results. Each source is weighted according to the inverse square of the noise. The weightings are therefore independent of stellar mass and UV-continuum slope β.
- Both the bootstrap and formal uncertainties are quoted on the result (presented first and second, respectively).
- The 1.2 mm continuum flux predicted from the consensus z ∼ 2–3 IRX–stellar mass relationship weighting individual sources in exactly the same way as for the measured 1.2 mm continuum flux. This column should therefore be directly comparable with the column directly to the left, i.e., giving the measured flux.
- Assuming a standard modified blackbody SED with our evolving dust temperature model and accounting for the impact of the CMB on the measured flux (da Cunha et al. 2013).
- Results do not depend on the assumed far-IR SED template.

With these inputs, the fiducial z ∼ 0 IRX–β relation we utilize in this study is the following:

\[ \text{IRX}_{z=0} = 1.7(10^{0.4(1.86β+1.85γ)}) - 1 \]  \hspace{1cm} (B2)

Despite the significant amount of evidence pointing to a grayer Calzetti-like extinction curve for high-mass galaxies (Reddy et al. 2006; Daddi et al. 2007; Pannella et al. 2009), at least some lower-mass mass galaxies appear to show a steeper SMC-like extinction curve (Baker et al. 2001; Reddy et al. 2006, 2010; Siana et al. 2008, 2009).

Using the observational results of Lequeux et al. (1982), Prevot et al. (1984), and Bouchet et al. (1985) (see also Pei 1992; Pettini et al. 1998; Gordon et al. 2003), we earlier obtained the following representation of the SMC extinction relation in Bouwens et al. (2016): A_FUV = 1.1(β + 2.23). To make this extinction relation more consistent with the one obtained from the Overzier et al. (2011), Takeuchi et al. (2012), and Casey et al. (2014) results, we adjust the β intercept to be −1.85. This results in the following relation:

\[ \text{IRX}_{SMC} = 1.7(10^{0.4(1.1(β+1.85)}} - 1) \]  \hspace{1cm} (B3)

One other IRX–β relationship we compare with in the present study is the canonical Meurer et al. (1999) IRX–β relation:

\[ \text{IRX}_{M99} = 1.7(10^{0.4(1.99β+2.23)}} - 1) \]  \hspace{1cm} (B4)

Appendix C
Comprehensive Presentation of Stack Results

The purpose of this appendix is to provide a much more comprehensive presentation of the stack results from ASPECS than is convenient for the main text. Tables 9–11 show our results for z ∼ 2–10 samples split by stellar mass, UV-continuum slope β, and apparent magnitude in the UV. The stack results are alternatively presented including or excluding those individually detected at >4σ.
Table 10
IRX versus Apparent Magnitude in the Rest-frame UV (m_{UV,AB})

| m_{UV} | Number of Sources | log_{10}M_{bol}/M_{\odot} | \beta_{med} | f_{2.2mm}(\mu Jy)^a | Measured | Predicted |
|--------|-------------------|---------------------------|-------------|---------------------|----------|-----------|
| <25    | 35                | 9.5                       | -1.4        | 92 \pm 8 \pm 52    | 171      | 24        | 108       |
| <25 (ind. <4\sigma) | 29                | 9.4                       | -1.5        | 12.5 \pm 3          | 99       | 14        | 43        |
| 25–31  | 610               | 8.4                       | -1.8        | 4.7 \pm 0.6         | 18       | 2         | 3         |
| All    | 645               | 8.5                       | -1.7        | 8.4 \pm 0.3         | 24       | 3         | 7         |
| <26    | 33                | 9.1                       | -1.5        | 13 \pm 8 \pm 10    | 11442    | 124       | 38        |
| 26–31  | 668               | 7.9                       | -2.1        | 0.1 \pm 0.7         | 4        | 0         | 1         |
| All    | 701               | 7.9                       | -2.1        | 0.5 \pm 0.7         | 387      | 5         | 2         |

Notes.

a Calculated identically to the columns in Table 9, but using the subdivisions of sources indicated in the rows of this table.

Table 11
IRX versus \beta

| \beta | Number of Sources | log_{10}M_{bol}/M_{\odot} | \beta_{med} | f_{2.2mm}(\mu Jy)^b | Measured | Predicted |
|-------|-------------------|---------------------------|-------------|---------------------|----------|-----------|

Notes.

a This column presents stack results. Each source is weighted according to the inverse square of the noise. The weightings are therefore independent of stellar mass and UV-continuum slope.

b Both the bootstrap and formal uncertainties are quoted on the result (presented first and second, respectively).

c The 1.2 mm continuum flux predicted using the M99 or SMC IRX–\beta relationship weighting individual sources in exactly the same way as for the measured 1.2 mm continuum flux, so these two quantities should be directly comparable.

d Assuming a standard modified blackbody SED with our evolving dust temperature model and accounting for the impact of the CMB on the measured flux (da Cunha et al. 2015).

e Results do not depend on the assumed far-IR SED template.
Appendix D
Sensitivity of IRX versus Stellar Mass Relation to Stellar Population Model

While exploring the relationship between IRX and stellar mass, we experimented with the use of different codes to estimate the stellar mass for individual sources over our HUDF ASPECS field. As found, e.g., in Appendix A, stellar population codes like MAGPHYS (da Cunha et al. 2008) and PROSPECTOR (Leja et al. 2017) find ~0.12 dex higher stellar masses in general than the FAST (Kriek et al. 2009) stellar population we use for our fiducial stellar mass estimates.

Our determination of the IRX versus stellar mass relation can potentially depend on the stellar population modeling code we use to estimate the stellar masses of specific sources. To investigate the dependence on the stellar mass estimates, we made use of the stellar mass estimates that Leja et al. (2019) provide for sources in our sample to $z \sim 2.5$ from PROSPECTOR (for every case where a match can be found) and rederive the stacked IRX versus stellar mass relation at $z = 1.5-3.5$. The best-fit values we find for $M_\star$ and $\alpha$ as applied to Equation (8) is $10^{9.63 \pm 0.12} M_\odot$ and $1.37^{+0.18}_{-0.15}$ respectively, and is shown with the blue solid circles and light-blue power-law fit in Figure 22. The derived relationship is significantly steeper than our fiducial determination shown with the red solid points and red shaded region, with a much lower implied IRX at stellar masses $<10^{9.5} M_\odot$.
