Application of plant extracts and *Trichoderma harzianum* for the management of tomato seedling damping-off caused by *Rhizoctonia solani*

Seeding production under smallholder farming systems can be negatively affected by both abiotic and biotic factors. Seeding damping-off caused by *Rhizoctonia solani* is one of the major biotic factors which causes significant yield reduction. Management is mainly based on the application of synthetic fungicides and cultural practices. However, both methods have limitations which result in their inefficiency. Several studies have reported on the use of plant extracts and biological control to manage plant diseases. The aim of this study was to formulate an effective and practical approach to manage tomato seedling damping-off using extracts of *Monsonia burkeana* and *Moringa oleifera* and a biological control agent *Trichoderma harzianum*. The efficacy of both extracts was investigated under laboratory conditions to determine the most suppressive concentration to *R. solani* growth. Methanolic extracts from both plants significantly suppressed pathogen growth at different concentrations. *M. burkeana* significantly reduced *R. solani* growth at 8 g/mL (71%) relative to control whilst *M. oleifera* extract reduced pathogen growth by 60% at a concentration of 6 g/mL. The highest suppressive concentrations were further evaluated under greenhouse conditions to test their efficacy on seedling damping-off. In damping-off treatments, both plant extracts and *T. harzianum* also significantly reduced (p = 0.5) pre- and post-emergence damping-off incidence. *M. burkeana* recorded the highest suppression at 78%, followed by *M. oleifera* at 64%. *Trichoderma harzianum* reduced incidence of damping-off by 60% and this was higher than both plant extract treatments.

**Significance:**
- The use of *M. burkeana* and *M. oleifera* extracts and *T. harzianum* effectively suppressed pathogen growth and disease incidence and can be used to reduce the use of synthetic pesticides that are harmful to the environment and human health.
- Application of plant extracts and biological control agents as possible alternatives to synthetic fungicides is considered a sustainable and affordable practice for smallholder farmers.

**Introduction**

Vegetable production is a major farming activity for smallholder farmers in the Limpopo Province of South Africa as it contributes to food security and improved livelihoods for rural communities. Production can however be negatively impacted by both biotic and abiotic factors, with diseases causing major yield losses. High incidences of soil-borne diseases such as damping-off and root rot that occur during seedling stage can cause crop losses of 60–90%.1 *Rhizoctonia solani* Kuhn is an important soil-borne fungal pathogen that is capable of causing diseases on a wide range of plants under favourable environmental conditions.1 It is a facultative parasite that is very competitive against other soil-borne organisms.2 Its survival in infected soils is mainly due to the formation of sclerotia for long-term survival without a host.2 Germination of sclerotia which takes place in the presence of a susceptible host, results in the infection and spread of disease.1 The tomato plant is highly susceptible to *R. solani* during different growth stages, with seedlings being particularly susceptible to attack by this pathogen.4,5 At seedling stage, plants are more susceptible to *R. solani* infection due to reduced resistance mechanisms which normally emerge at the adult stage of plant growth.2 Seeding blight, root and hypocotyl rots are typical symptoms of *R. solani* infection in highly susceptible plants, especially when planted under suitable environmental conditions.5

Management of damping-off is mainly through growth media treatment with chemicals or heat,6 seed treatment, use of cultural practices and planting of resistant cultivars.7 However, all control measures have limitations which result in their inability to provide significant disease control. For example, the detrimental effect of soil fumigants on the environment and human health has resulted in their ban in agricultural production systems.8 Also, development of resistant cultivars against damping-off has proven difficult due to the diversity of soil pathogens involved in seedling infection.6 Seed treatment, on the other hand, is more efficient during seed germination7 and this is normally lost during seedling stage10. For these reasons, there is a growing need to identify and develop new approaches for the control of *R. solani* damping-off based on the sustainable management of crops and application of environmentally friendly compounds, especially for smallholder farmers.

In recent years, alternative control measures such as plant-based bioactive compounds in the form of extracts have been studied and have provided promising results, especially against soil- and seed-borne diseases.11-13 Plants produce compounds which have been shown to inhibit the growth and development of diseases caused by bacteria, fungi and other disease-causing organisms.14-15 Plant extracts have the ability to induce defences in plants, resulting in an effective tolerance against pathogen attack.16 Therefore, the presence of these antimicrobial compounds in plants provides an opportunity for their use in the management of pests and diseases as environmentally safe alternatives to synthetic pesticides.17
Effect of *M. burkeana* and *M. oleifera* extracts on mycelial growth of *R. solani*

Amounts of 0, 2, 4, 6, 8 and 10 g of the resultant suspension of each plant extract were separately dissolved in 10 mL sterile distilled water and thoroughly mixed before being added to 200 mL bottles and content containing PDA. Bottles were then autoclaved at 121 °C for 15 min. In the previous studies, heat was found to have no effect on the ability of both extracts to suppress pathogen growth. The extract amended PDA was poured into 80-mm Petri plates and left to solidify overnight. Disks of 5 mm in diameter were cut from 7-day-old actively growing *R. solani* cultures and were placed at the centre of extract-amended PDA Petri plates. Inoculated PDA Petri plates were then incubated at 25 °C under aseptic conditions for 7 days. Non-amended PDA plates served as control treatments. Pathogen colony growth diameter was measured using a transparent ruler after ±7 days. Mycelia growth inhibition was calculated using the formula:

\[
\text{Relative treatment effect (RTE) = } \left[ \frac{(T/C) - 1}{100} \right] \times 100
\]

where C is the average diameter of the fungal colony in control plates and T is the average diameter of the fungal colony in extracts-amended plates.

**Greenhouse experiment**

**Fungal inoculation and treatment preparation**

*Rhzoctonia solani* inoculum was prepared by soaking 240 g clean quartz in 75 mL of sterile, distilled water for 24 h in 500-mL Erlenmeyer flasks. Thereafter, 6.0 g yellow maize meal and 75 mL tomato juice were added to the flasks and autoclaved twice for two consecutive days. The autoclaved mixture was then inoculated with 20 discs of 7-day-old pure *R. solani* culture and incubated for 14 days at 25 °C. After incubation, the inoculum was oven dried at 50 °C for 14 days.

Tomato (cv. Money maker) was used as a test plant against *R. solani* seedling damping-off. Plant extracts were first tested for their effect on seed germination by soaking surface-sterilised tomato seeds in different concentrations of *M. burkeana* and *M. oleifera* extract solutions used in the laboratory and then determining the number of germinated seeds. The plant extracts were then confirmed to have no effect on seed germination and were further used for the greenhouse experiment.

Plastic pots (250 mm in diameter) were filled with pasteurised sand and Hygromix in a 3:1 (v/v) ratio. Four holes, 80 mm deep and 50 mm wide, were made and the media was artificially inoculated with 20 g *R. solani* inoculum in each hole. Inoculated growth media was moistened with 200 mL sterile distilled water and left to stand for 7 days before planting to allow the pathogen to establish in the soil. After 7 days, five surface sterilised seeds were planted in each pot, followed with soil drenching with plant extract concentrations. Concentrations of plant extracts that displayed pathogen growth suppression under in-vitro evaluation were used. These were 0.4, 0.6 and 0.8 g/mL for *M. burkeana* and 0.2, 0.4 and 0.6 g/mL for *M. oleifera*. Soil treatment with each plant extract solution was done once after 7 days of inoculation. Irrigation with tap water was applied once a week for 4 weeks. Each treatment was replicated four times and damping-off was determined by counting the number of non-geminated seeds and dead seedlings for pre- and post-emergence damping-off, respectively. Pathogen re-isolation was done from dead seedlings to confirm the presence of *R. solani*.

**Biotic control inoculum and treatment preparation**

*Trichoderma harzianum* inoculum was prepared following the same procedure used for *R. solani* and received the same amount of dried biocatalyst treatment 7 days after *R. solani* was established in the soil. Pots treated with *T. harzianum* and control treatment were irrigated with 100 mL tap water once every 2 days. Pre- and post-emergence damping-off were assessed and recorded as described:

\[
\text{Pre-emergence damping-off (％) = } \frac{\text{Number of diseased seeds}}{\text{Total number of seeds planted}} \times 100
\]
Post-emergence damping-off (%) = Number of diseased seedlings / total number of seedlings \times 100 \quad \text{Equation 3}

Efficacy of plant extracts of each treatment was evaluated as:

Relative treatment effect (RTE) = \left( \frac{\text{treatment}}{\text{untreated control}} - 1 \right) \times 100, \quad \text{Equation 4}

where reduction was expressed with a negative sign and stimulation or increase was expressed by a positive sign.

**Data analysis**

The experiment was laid down in a completely randomised design with six treatments and four replicates. Data were subjected to a partial ANOVA using SAS statistical program. Mean separation was achieved by using Fisher’s least significant difference test at a probability level of 5%. The responses of mean suppression to increasing M. burkeana or M. oleifera concentration levels (x-axes) were subjected to the lines of the best fit using MS Excel v. 2016. The maximum growth inhibition was measured at 71% and 60% for both M. burkeana and M. oleifera, respectively (Table 2). The maximum growth inhibition was measured at 71% and 60% for both M. burkeana and M. oleifera, respectively (Table 2).

**Results**

**Effect of M. burkeana and M. oleifera extracts on mycelial growth of R. solani**

All tested concentrations of both M. burkeana and M. oleifera reduced mycelial growth of R. solani when compared to control (Table 1). M. burkeana displayed the highest mycelial growth inhibition at a concentration of 8 g/mL (Table 2; Figure 1). With M. oleifera treatments, the highest pathogen growth suppression was obtained at 6 g/mL (Table 2; Figure 2). The maximum growth inhibition was measured at 71% and 60% for both M. burkeana and M. oleifera, respectively (Table 2).

![Figure 1: Quadratic relationship between percentage mycelia growth of Rhizoctonia solani and Monsonia burkeana plant extract concentration.](https://doi.org/10.17159/sajs.2020/7860)

![Figure 2: Quadratic relationship between mycelia growth of Rhizoctonia solani and Moringa oleifera plant extract concentration.](https://doi.org/10.17159/sajs.2020/7860)

**Greenhouse experiment**

Amendment of R. solani inoculated soil with different concentrations of M. burkeana and M. oleifera had a varying effect on damping-off incidences with treatments displaying low, moderate and high suppressive effect (Table 3 and Table 4). The same trend was also observed for T. harzianum treatments, in which the levels of suppression were different for both pre- and post-emergence damping-off. However, despite these variations, suppression was still higher than in the inoculated non-amended control. For example, at 0.6 g/mL, M. burkeana significantly reduced pre-emergence damping-off (78%), whilst the highest post-emergence damping-off reduction of 69% was recorded for 0.8 g/mL treatments. At a concentration of 0.4 g/mL, M. burkeana had no effect on damping-off incidence, resulting in high incidences of both pre- and post-emergence damping-off. Treating R. solani inoculated soil with T. harzianum also resulted in a relative reduction of pre-emergence (60%) and post-emergence damping-off (38%) (Table 3). However, reduction was lower when compared to M. burkeana treatment.

The three tested M. oleifera concentrations displayed a significant difference in their ability to reduce both pre- and post-emergence damping-off (Table 4). Treatment of infected soil with 0.2 g/mL of M. oleifera extract solution resulted in a significant reduction in both pre- and post-emergence damping-off incidence whilst 0.6 g/mL was only effective in reducing pre-emergence damping-off. Soil treatment with 0.4 g/mL had no effect on either pre- or post-emergence damping-off of tomato as there was no significant difference for this concentration compared with the non-amended control. A significant reduction in damping-off was also recorded where R. solani inoculated soil was amended with T. harzianum, resulting in 60% and 39% pre- and post-emergence damping-off reduction, respectively. To confirm differences between treatments, a relative treatment effect was also carried out.

**Table 1:** In-vitro effect of Monsonia burkeana and Moringa oleifera plant extract concentrations for optimal mycelial growth suppression of Rhizoctonia solani

| Plant extracts | Formula               | \( R^2 \) | \( x \) | \( Y \) | \( p \) |
|----------------|-----------------------|----------|--------|-------|------|
| M. burkeana    | \( y = 1.0134x^2 - 16.234x + 88.179 \) | 0.97     | 8.01   | 23.16 | 0.05 |
| M. oleifera    | \( y = 1.1384x^2 - 13.513x + 88.321 \) | 0.69     | 5.94   | 48.22 | 0.05 |

**Table 2:** Effect of Monsonia burkeana and Moringa oleifera on mycelial growth suppression of Rhizoctonia solani in vitro

| Treatment (g/mL) | \( M. burkeana \) | \( M. oleifera \) |
|------------------|-------------------|-------------------|
|                  | Mean (mm) | RTE (%) | Mean (mm) | RTE (%) |
| 0                | 85*       | –       | 85*       | –       |
| 2                | 68*       | –20     | 74*       | –13     |
| 4                | 34*       | –60     | 52*       | –54     |
| 6                | 26*       | –69     | 34*       | –60     |
| 8                | 25*       | –71     | 67* \(_{\text{nc}}\) | –21     |
| 10               | 27*       | –68     | 63*       | –26     |

Means in the same column followed by the same letter were not significantly different (\( p>0.05 \)) according to Fisher’s least significant difference test.

RTE, relative treatment effect = (treatment/untreated control) \times 100.
against the untreated control (Table 4). The results show that there was a significant difference amongst the concentrations of M. oleifera and biocontrol T. harzianum and their ability to reduce damping-off incidences. For example, although damping-off incidence in T. harzianum treated pots was slightly reduced with RTEs of 18% and 13% for pre- and post-emergence damping-off, respectively, these were still significantly higher than that for the control treatment. The RTE for M. oleifera treatments further shows that pre-emergence damping-off was reduced by 64% with a concentration of 0.2 g/mL, whilst post-emergence damping-off was reduced by 31% in 0.6 g/mL relative to untreated control (Table 4).

The efficacy of the treatments corroborates previous research; relative treatment effect (RTE) = (treatment/untreated control) × 100.

Means in the same column followed by the same letter were not significantly different (p ≥ 0.05) according to Fisher’s least significant difference test.

Table 3: Comparing the effect of Monsonia burkeana extract and Trichoderma harzianum on pre- and post-emergence damping-off caused by Rhizoctonia solani under greenhouse conditions

| Treatment (g/mL) | Pre-emergence damping-off | Post-emergence damping-off |
|------------------|---------------------------|---------------------------|
|                  | Mean | RTE (%) | Mean | RTE (%) |
| Untreated control| 0.4a | –       | 0.7a | –       |

Means in the same column followed by the same letter were not significantly different (p ≥ 0.05) according to Fisher’s least significant difference test.

RTE, relative treatment effect = (treatment/untreated control) × 100.

Discussion

Monsonia burkeana and M. oleifera plant extracts separately reduced the incidence of damping-off under greenhouse conditions. T. harzianum as a biological control agent was also found to be effective in reducing damping-off in vivo. The efficacy of the treatments corroborates previous studies which demonstrated the ability of M. burkeana, M. oleifera and T. harzianum to reduce the disease severity and disease incidence of fungal soil-borne diseases. Besides reducing disease severity, plant extracts have also been shown to increase shoot and root mass.

Most medicinal plants – including M. burkeana and M. oleifera – contain a number of phytochemicals that exhibit antimicrobial activity, and inhibit fungicidal capabilities, toxic antibiotics and mycoparasitism. The degree of reduction of damping-off by T. harzianum is possibly attributed to the secretion of antibiotics by the antagonist or other inhibitory substances produced by the antagonistic chemical compounds such as geodinc, terricin and terric acids. For example, certain Trichoderma species colonise and penetrate plant root tissues and initiate a series of morphological and biochemical changes in the plant, which are considered to be part of the plant defence responses, which eventually lead to an induced systemic resistance in the entire plant.

Although the main focus of the current study was on the effects of plant extracts and T. harzianum on disease incidence, it was also observed that the level of suppression differed between extracts. For example, M. burkeana extract was more effective in suppressing both pre- and post-emergence damping-off incidence than the extract obtained from M. oleifera. Despite their ability to suppress pathogen growth to reduce disease incidence, many reports have shown that this occurs to varying degrees and is mainly dependent on the plant species and its interaction with the pathogen at physiological and molecular levels. For example, a report by Hassanein et al. indicated greater efficacy of neem (Azadirachta indica) extracts when compared to other extracts, probably due to different chemical compounds in neem that had greater antifungal activities. This phenomenon also applies to biocontrol agents, with reports showing that their degree of effectiveness varies according to the nature, quality and quantity of antibiotics or inhibitory substances secreted.

Conclusion

The current findings demonstrate the effectiveness of both M. burkeana and M. oleifera extracts and T. harzianum in the management of soil-borne diseases in seedling production. The tested plant extracts are easily accessible to smallholder farmers, they are easy to process and are environmentally friendly; they can therefore be used as possible parts of an integrated control measure against seedling damping-off. In this study, both plant extracts and T. harzianum were applied separately; further studies on their combined application are recommended to determine their synergistic relationship. Further research is also recommended to determine the impact of plant extracts on the soil rhizosphere microbiome, especially on beneficial microorganisms.
