In this report, we investigate dynamical robustness of a complex network to noise injected through one of its nodes. We focus on synchronization of coupled nonlinear systems and, as a special instance, we address the classical consensus protocol for linear integrators. We establish an exact closed-form expression of the synchronization error for the consensus protocol and an approximate result for chaotic units. While structural robustness is known to be significantly affected by attacks targeted to network hubs, our results posit that dynamical robustness is controlled by both the topology of the network and the dynamics of the units. We provide examples where hubs perform better or worse than isolated nodes.

Communication networks, transportation infrastructures, and power grids are all subjected to failures that often involve a significant portion of the system despite the local nature of the initial fault. Thus, error and attack tolerance, cascading failures, and, in general, robustness of complex networks have been the body of intense research.

To quantify network robustness, generally defined as the ability of the network to withstand accidental events, different measures have been proposed: conditional connectivity³, restricted connectivity⁴, super connectivity⁵, fault diameter⁶, expansion parameter⁷, isoperimetric number⁸, and natural connectivity⁹. Other measures of network robustness have been developed in the theoretical framework of statistical physics and percolation theory¹⁰–¹³. These efforts seek to elucidate the effect of the removal of a fraction of nodes (or links) on characteristic properties of a network, such as its diameter, largest component, and efficiency.

Such investigations have demonstrated that topology is a determinant of robustness, whereby heterogeneous (scale-free) networks are highly robust against random attacks, which can instead severely impact homogeneous networks. Nevertheless, targeted attacks to hubs of scale-free networks can dramatically affect network properties. Indeed, the collapse of the entire network can be caused by a single node whose failure propagates to neighboring nodes promoting cascading damages and avalanches¹⁴–¹⁷. This phenomenon is well explained by modeling the dynamics of flow redistribution on the network to unveil the mechanisms underlying the large breakdowns observed in real systems, such as the Internet or electrical power grids¹⁶,¹⁷.

Most of the existing studies deal with the robustness of the network structure and are based on the assumption that the failure of a node (or a fraction of nodes) is equivalent to a complete loss of its (their) functionalities. Here, we take a different approach to understand the effect of a partial malfunctioning on the dynamics of the network. This scenario is expected to be relevant for biological networks¹⁸, distributed sensors¹⁹ and, in general, complex systems composed of coupled dynamical units²⁰. Notably, robustness with respect to the system dynamics has been recently investigated in²¹, where networks of diffusively coupled second-order periodic oscillators are considered and node failure is modellled as the inactivation of oscillations (quenching).

In this report, we study networks of identical coupled dynamical units (including chaotic oscillators) and elucidate on the effect of partial malfunctioning of a network node on synchronization. We model the phenomenon of node failure by injecting noise into the dynamics of a node. In particular, we consider a white Gaussian signal with zero-mean and variance σ². Increasing the noise level, that is, σ², the synchronization error increases and the units may eventually leave the basin of attraction for sufficiently strong noise. Our primary objective is to establish a mathematical framework for assessing dynamical robustness and investigating the complex interplay between network topology and node dynamics. We derive tractable expression for the synchronization error and introduce a novel network parameter, which allows to rank the nodes in terms of their impact on the network dynamical robustness. We analyze four representative dynamics for coupled dynamical systems and explore different network topologies to illustrate the proposed methodology and demonstrate that both the topology and the dynamics are determinants of node ranking.

Results

Evaluation of dynamical robustness to noise injection into a node.

Here, we establish a mathematical framework for assessing dynamical robustness and investigating the interplay between network topology and node dynamics. In particular, we consider a network of N dynamical units, which synchronize in the absence of noise. Dynamical robustness is quantified through the synchronization error as a function of the noise variance. To compute such error, we first derive the (stochastic) dynamical equations of the transverse modes of the system. From these equations, we relate the synchronization error to the statistical properties of the transverse modes and, more in detail, to their joint moments. Based on the derived expression of the error, we then introduce a novel network parameter, which allows to rank the nodes in terms of their impact on the network dynamical robustness.

We consider a network of N dynamical units, described by the following coupled equations:

$$\dot{x}_i = F(x_i) - \kappa \sum_{j=1}^{N} g_{ij} H_k(x_j) + \xi_i H_{\eta_1}$$

(1)

for $i = 1, \ldots, N$, where $x_i \in \mathbb{R}^m$ represents the state vector of the $i$th node, $F$ the individual dynamics, $\kappa$ the coupling coefficient, and $\xi_i$ the $j$th entry of the network Laplacian $G$, and $H_k$ the coupling function. The term $\eta$ is a zero-mean Gaussian white noise of variance $\sigma^2$ and $H_{\eta_1} \in \mathbb{R}^m$ is a vector of zeros and ones that models how the noise influences the dynamics of a node. We hypothesize that the noise acts on a single node, say node $h$, so that $\xi_i = 1$ if $i = h$ and $\xi_i = 0$ if $i \neq h$.

To study the effect of the noise intensity and injection site on the network synchronization, we suppose that the network synchronizes in the absence of the noise and evaluate the synchronization error with respect to the noise variance. We consider the following synchronization error:

$$\mathcal{E}_h = \frac{1}{N^2} \sum_{i,j} \langle |x_i - x_j|^2 \rangle_t$$

(2)

where $\langle \cdot \rangle_t$ indicates averaging with respect to $t$ in a defined observation window. For a sufficiently large observation window and assuming the system to be ergodic, the error (see Methods) is rewritten as:

$$\mathcal{E}_h = \frac{2}{N^2} \sum_{i=1}^{N} \sum_{k,l=2}^{N} T_{ik} T_{jl} \mathbb{E}[y_i^T y_l]$$

(3)

where $\mathbb{E}[\cdot]$ is the expected value, $T$ contains the right eigenvectors of the graph Laplacian $G$, and $y_k$ for $k = 2, \ldots, N$ are the transverse modes (see Methods).

Now, we distinguish between a special case of synchronization, namely the classical consensus problem, for which an exact formula of $\mathbb{E}[y_i^T y_l]$ is derived, and the more general case of synchronization of chaotic units, for which an approximation of $\mathbb{E}[y_i^T y_l]$ is established.

We first consider a consensus problem, that is, $x_i \in \mathbb{R}$ and $F = 0$. In this case (see Methods), $\mathbb{E}[y_i y_l]$ is given by:

$$\mathbb{E}[y_i y_l] = \frac{(T_{ik} - N^{-1} \sum_j T_{ik}) (T_{jl} - N^{-1} \sum_j T_{jl}) \sigma^2}{\kappa (T_{ik} + y_j)}$$

(4)

As expected, $\mathcal{E}_h$ in (3) is linear with respect to $\sigma$ and both the network topology and the node dynamics are important in shaping the network dynamical robustness.

We now consider the case of synchronization of chaotic units. To this aim, we rewrite the dynamical equations of the transverse modes (see Methods) in terms of the scaled Gaussian noise $\eta_i = (T_{ik} - N^{-1} \sum_j T_{ik}) \eta$ (with zero mean and variance $(\sigma_k^2)^2 = (T_{ik} - N^{-1} \sum_j T_{ik}) \sigma^2$), and we numerically compute the evolution of the modes for each value of $\sigma_k^2$ and calculate $\mathbb{E}[y_i^T y_l]$ as a function of $\sigma$.

Consistently with the consensus problem, numerical simulations show that $\mathbb{E}[y_i^T y_l]$ is proportional to $\sigma_i^2 \sigma_j$. Thus, we define the function $\mathcal{M}$ so that $\mathcal{M}(y_i, y_l) = \frac{\mathbb{E}[y_i^T y_l]}{\sigma_i^2 \sigma_j}$. Since the transverse modes only differ for the term $x_k = \kappa y_k$, in the following we use the notation $\mathcal{M}(x_k, x_l)$. Notably, for the consensus problem, such function reduces to $1/(x_k + x_l)$. In general, $\mathcal{M}$ depends only on the node dynamics, the coupling function, and the modality for which noise is injected into the node.

To quantify the effect of noise injected in the network at the $h$th node, we define the normalized quantity $\rho_h = \frac{\mathcal{E}_h}{\mathcal{E}_h}$, which takes the following general form:

$$\rho_h = \frac{2}{N^2} \sum_{i=1}^{N} \sum_{k,l=2}^{N} T_{ik} T_{jl} \mathbb{E}[y_i^T y_l] \mathcal{M}(x_k, x_l)$$

(5)

Injection of noise in correspondence of nodes with small $\rho_h$ leads to smaller synchronization error, compared to the case when noise is applied to nodes with large $\rho_h$. Hence, the network is more robust to noise injected at sites with low $\rho_h$. We remark that $\rho_h$ depends on the topology of the network and on the dynamics of the unit. In contrast with structural robustness, which depends only on topology, we find that dynamics is an essential element of dynamical robustness.

Interplay of topology and dynamics. We illustrate the concept of dynamical robustness through some examples. We consider two types of networks, that is, scale-free (SF) and Erdos-Renyi (ER) networks, and four different dynamics for the network units: a simple integrator, a Chua’s circuit, a Rossler’s system, and a Chen’s system (see Methods). These systems are selected on the basis of an exhaustive analysis on a multitude of dynamical systems (not reported here) to highlight the salient features of dynamical robustness that are unveiled by our study. We first investigate the agreement between our theoretical arguments and numerical or experimental data and then analyse $\rho_h$ for some networks with a large number of nodes.

We consider a SF and an ER network with $N = 100$ nodes and average degree equal to 2 (see Methods). The coupling coefficient $\kappa$ is chosen so that the networks synchronize in the absence of noise and $\kappa y_2$ does not vary. We integrate equation set (1) and evaluate the synchronization error (2). As expected, we find that $\mathcal{E}_h$ is linear in $\sigma$ and we define $\delta_h = \frac{\rho_h}{\mathcal{E}_h}$ to compare the theoretical results based on $\rho_h$ with numerical findings based on $\delta_h$.

In Fig. 1, we report $\rho_h$ vs $\delta_h$ for both types of networks. The agreement between simulations and theoretical expectations is almost perfect; theoretical expectations correctly reproduce the ranking of nodes based on the network performance in the presence of noise. In fact, nodes can be equivalently ranked according to either the value of $\rho_h$ or of $\delta_h$.

Next, we compare theoretical expectations with a network of real electronic oscillators. The experimental setup is that described in Methods and consists of a network of six Chua’s circuits coupled according to the network topology shown in Fig. 2(a). Fig. 2(b) shows the comparison between $\rho_h$ (theoretical expectation) and $\delta_h$ (experimental data) for each network node, demonstrating a very good agreement between theoretical and experimental results.

To offer some statistical relevance to the proposed method, we numerically analyze $\rho_h$ for networks with a large number of nodes. In particular, we consider SF and ER networks with $N = 1000$ nodes and average degree equal to 2. Fig. 3 illustrates the results for four case studies. In panels (a,b,c,d), we display the value of $\rho_h$ ordered in ascending order for a SF and an ER network. In panels (e,f,g,h), we display the degree of node $h$, labelled as $k_h$, vs. $\rho_h$. The network dynamics are those of Fig. 1. SF networks demonstrate worse
performance than ER networks for most of the nodes in the case of consensus and Chua’s dynamics. Instead, in the case of Rossler’s systems, the SF network performs better than the ER network with the exception of a small percentage of nodes, which are the network hubs. In the case of Chen’s systems, the ER network performs better than the SF network for about half of the nodes.

Based on the premise that the precise ranking of the nodes in terms of dynamical robustness is dictated by ρ_u, we observe some general trends in the node ranking with respect to topological measures, such as the node degree. Specifically, for the consensus problem and for the network of Chua’s circuits, we find that nodes with high degree have better robustness to noise as compared to nodes with lower degree. On the contrary, for networks of Rossler’s systems, the opposite holds, whereby nodes with low degree display better robustness to noise than nodes with high degree. In the case of Chen’s systems, the correlation between ρ_u and ρ_h is weaker. In fact, the nodes that display poor dynamical robustness are those with high degree. Yet, there are also several low degree nodes with limited performance as shown in panel (h).

Our analysis demonstrates that robustness to noise is the result of the interplay between dynamics and topology, whereby dynamical robustness with respect to noise injected in select node cannot be inferred only on the basis of its degree or other topological measures such as, for instance, eigenvector centrality. To further elucidate this interplay, we report in Fig. 4 the function $M(x_h, x_l)$ for the different systems investigated. We distinguish between functions $M$ that are monotonically decreasing with respect to each of their variables $x_h$ and $x_l$ and those that are not. Specifically, we define as $M(x_h, x_l)$ the family of functions that are monotonically decreasing with respect to each of the two variables. Thus, for consensus and Chua’s circuit $M(x_h, x_l)$, while for Rossler’s and Chen’s dynamics $M(x_h, x_l)$. We observe that this difference is crucial to determine the opposite behaviors found in the correlation between node degree and node robustness, for instance, for the Chua’s circuit and the Rossler’s system.

The interplay between topology and dynamics in dynamical robustness can be further illustrated through the analysis of an exemplary network, which allows for the derivation of closed-form expressions. In particular, we focus on a star network topology for which we can find ρ_u for every network node. In this network, one node, labelled as node 1 and referred to as the hub, is connected to all the other nodes of the network, referred to as the leaves. All the leaves have degree equal to one, while the hub has degree $N - 1$. The star network Laplacian has eigenvalues equal to $\gamma_1 = 0, \gamma_2, ..., \gamma_{N-1} = 1$, and $\gamma_N = N$. For such network, lengthy, but trivial, calculations lead to the following formulas for $\rho_1$ and $\rho_{2, ..., N}$:

$$\rho_1 = \sqrt{\frac{2}{N} \left( 1 - \frac{1}{N} \right)} M(x_N, x_N)$$

$$\rho_{2, ..., N} = \sqrt{\frac{2}{N} \left( 1 - \frac{1}{N-1} \right)} M(x_2, x_2) + \frac{2}{N^2(N-1)} M(x_N, x_N)$$

These expressions are particularly simple since they depend only on two values of the function $M$, that is, $M(x_2, x_2)$ and $M(x_N, x_N)$. It is easy to note that $\rho_1$ is greater than $\rho_{2, ..., N}$ (that is, the leaves perform better than the hubs) if and only if $M(x_N, x_N) > M(x_2, x_2)$. Given the form of $M$ for the Chen’s system, $M(x_N, x_N)$ can be either greater or lower than $M(x_2, x_2)$, which implies that according to the values of $x_2$ and $x_N$ (and, ultimately, on the coupling strength $k$), the leaves can perform better than the hub or vice versa. This is illustrated in Fig. 5 for a star network of $N = 5$ Chen’s systems. For $k = k_1 = 30$, the hub of the network has superior dynamical robustness performance than peripheral nodes. In fact, $k_1/2$ and $k_1/3$ are such that $M(k_1/2, k_1/3) < M(k_1/2, k_1/3)$ (panel...
(a), black circles). Instead, for $k = k_2 = 60$ the opposite holds, $\mathcal{M}(\kappa_2^2, \kappa_2^2) > \mathcal{M}(\kappa_2^2, \kappa_2^2)$ (panel (a), red circles), and the leaves outperform the hub.

The analysis of the star network confirms that, depending on the shape of $\mathcal{M}$, the same topology may display opposite correlations between node degree and node robustness. In the general case (shown in Fig. 1(h)), for which $\mathcal{M} \neq \mathcal{D} \mathcal{M} \mathcal{D}$, a clear correlation between node degree and node robustness cannot be readily established.

**Discussion**

Here, we have introduced a mathematical framework to understand the dynamical robustness of complex networks to noise injected into their nodes. The approach lends itself to the formulation of a novel performance metric, see Eq. (5), which allows for the quantification of dynamical robustness as a function of network topology and node dynamics. We have considered a spectrum of dynamics and topologies to demonstrate the complex response of networks to noise injection. In contrast with structural robustness, where attacks targeted to hubs are generally more severe than removal of low-degree nodes, injection of noise into hubs may be more or less dangerous than injection of noise into low-degree nodes depending on the unit dynamics. Experimental evidence of this second scenario has been reported for small networks (limited to up to six nodes) in25. A similar role of low-degree nodes has been also observed in21, where periodic oscillators have been considered and failure has been modelled through quenching rather than injected noise. Finally, we mention that another measure of network robustness in terms of the dynamical properties of the network has been introduced in30, where dynamic vulnerability, that is, the collective response of the network to a finite time perturbation into a single node, is studied for a

---

**Figure 3** | Numerical results for networks with $N = 1000$ nodes: (a,b,c,d) $\rho_h$ and (e,f,g,h) degree of node $h (k_h)$. The dynamics of a unit is: (a)-(d) consensus; (b)-(e) Chua’s circuit; (c)-(f) Rossler’s system; and (d)-(h) Chen’s system. The coupling coefficient $k$ is 1 for consensus; 14.45 and 16.22 for SF and ER networks of Chua’s circuits; 1.81 and 2.03 for SF and ER networks of Rossler’s systems; and 14.88 and 17.49 for SF and ER networks of Chen’s systems.

**Figure 4** | The function $\mathcal{M}(\kappa_2^2, \kappa_2^2)$ for (a) consensus; (b) Chua’s circuit; (c) Rossler’s system; and (d) Chen’s system. To better visualize the specific features of each function, the range for which they are reported is not the same.
network of Rossler's systems. The conclusion that the hubs are not the more vulnerable nodes is in agreement with our results.

We have found that networks of Chua's circuits and Rossler's systems are representative of two opposite behaviors that can be exhibited by a network in terms of its dynamical robustness to noise. Specifically, we have demonstrated that, in networks of Chua's circuits, the ranking of the nodes mirrors the node degree, while, in networks of Rossler's systems, low-degree nodes are more robust to noise injection. Furthermore, we have observed (as in the case of networks of Chen's systems) that there are scenarios in which a clear correlation between node degree and node robustness cannot be established. The different behaviors exhibited by these systems are explained by the shape of the function $M$ in Eq. (5). For systems with $M \in \mathbb{R}^{3 \times 3}$, we have observed a degree-correlated behavior (that is, higher degree nodes have higher dynamical robustness performance than lower degree nodes). On the other hand, for systems with $M \in \mathbb{R}^{4 \times 4}$, which we classify as dynamical robustness class II systems, a clear correlation between node degree and node robustness cannot be established. For dynamical robustness class II systems, different scenarios may arise depending on the system (topological and dynamical) parameters, including degree-correlated and anti-degree-correlated behaviors. Thus, our main conclusion is that dynamical robustness is affected by both the topology of the network and the dynamics of the units and that the parameter $\rho_h$ is a suitable measure for node dynamical robustness.

**Methods**

**Dynamical equations of transverse modes.** Using the Kronecker algebra, Eqs. (1) can be rewritten in the compact form:

$$\dot{x} = F(x) - \kappa G \otimes H_0(x) + \Xi \otimes H_0 \eta$$

(7)

where $x = [x_1, x_2, \ldots, x_N]^T$, $H_0(x) = [H_0(x_1), H_0(x_2), \ldots, H_0(x_N)]^T$, and $\Xi = [\xi_1, \xi_2, \ldots, \xi_N]^T$.

Due to the presence of the noise, the oscillators cannot synchronize, that is, the solution $x_i = \ldots = x_N$ is not feasible. Thus, we define the synchronization error with respect to a virtually synchronous state $\bar{x}$ whose evolution proxies the individual node dynamics when the noise is uniformly distributed in the network: $\bar{x} = F(\bar{x}) + N^{-1} H_0 \eta$.

We now linearize Eq. (7) around the synchronous state $\bar{x}$ to obtain

$$\dot{\zeta} = [I_N \otimes DF - \kappa G \otimes DH_0] \zeta + \Xi \otimes H_0 \eta$$

(8)

where $\zeta = x - I_N \otimes \bar{x}$, $1 \in \mathbb{C}^N$ is the vector of all ones, Jacobians are evaluated on the synchronous state, and $\Xi = [\xi_1 - \bar{x}, \xi_2 - \bar{x}, \ldots, \xi_N - \bar{x}]^T$. To study Eq. (8), we define a new set of state variables $y = T^{-1} \otimes \zeta$, where $T$ contains the right eigenvectors of the graph Laplacian $G$ and $\bar{x}$ is the identity matrix of order $m$. For the sake of simplicity, we suppose that the network is undirected so that $G$ is symmetric and $T^{-1} = T^T$. Since $T^T \Xi = [T_{1h} - \sum_j T_{j1} / N, \ldots, T_{Nh} - \sum_j T_{nj} / N]^T$, we have:

$$y_k = [DF - \kappa G \otimes DH_0 \eta]_k + [T_{kh} - N^{-1} \sum_j T_{jh}] \eta_j$$

(9)

where $\eta_j$ is the vector of all ones, Jacobians are evaluated on the synchronous state, and $\Xi = [\xi_1 - \bar{x}, \xi_2 - \bar{x}, \ldots, \xi_N - \bar{x}]^T$. The synchronization error (2) is now rewritten in terms of the transverse modes. In fact, since $\frac{1}{N} \sum_j (\bar{x}_j - x_j)^2 = \frac{1}{N} \sum_j (\bar{x}_j - \bar{x})^2$, the average trajectory that can be approximated as $\bar{x} = \bar{s} + \bar{y}_1$, and $\xi_k = \bar{x} - s = \sum_i T_{ik} y_i$, the error (2) can be rewritten as:

$$\dot{\bar{E}} = \frac{2}{N} \left( \sum_{i=1}^{N} \left( \sum_{j=1}^{N} T_{ij} y_j \right)^2 \right)$$

(10)

Now, we illustrate the form of the dynamical equations of the transverse modes and the expression of $E[y_1 y_1]$ for the two cases investigated (the classical consensus problem and the more general case of synchronization of chaotic units).

For the consensus problem ($x \in \mathbb{R}$ and $F = 0$), Eq. (9) becomes

$$\dot{y}_k = -\kappa y_k + \frac{T_{kh} - N^{-1} \sum_j T_{jh} y_j}{\eta}$$

(11)

By noting that for a continuous-time system in the form:

$$\dot{\bar{z}}_1 = -a_1 \varepsilon_1 + \eta_1$$

$$\dot{\bar{z}}_2 = -a_2 \varepsilon_2 + \eta_2$$

(12)

with $a_1, a_2 > 0$ and $\eta_1$ and $\eta_2$ zero-mean Gaussian processes with variance $\sigma_1$ and $\sigma_2$, respectively, $E[y_1 y_1]$ is given by

$$E[y_1 y_1] = \frac{\left( T_{kh} - N^{-1} \sum_j T_{jh} \eta_j \right)^2}{\sigma^2}$$

In the case of synchronization of chaotic units, Eq. (9) is rewritten in terms of the scaled Gaussian noise $\tilde{y}_k = (T_{kh} - N^{-1} \sum_j T_{jh} \eta_j)$ with zero mean and variance $(\tilde{y}_k)^2 = (T_{kh} - N^{-1} \sum_j T_{jh} \sigma_j)^2$, that is,

$$\tilde{y}_k = [DF - \kappa G \otimes DH_0 \eta]_k + \Xi \otimes H_0 \eta$$

(13)

In this case, $E[y_1 y_1]$ is calculated from Eq. (13). In particular, we numerically integrate Eq. (13) with the Euler-Maruyama integration method, we compute the evolution of the modes for each value of $a_j$ and calculate $E[y_1 y_1]$ as a function of $\sigma$.

**Model equations.** The network for the consensus problem is described by Eqs. (1) with $m = 1$, $x_0 \in \mathbb{R}$, $F(x_0) = 0$, and $H_0(x) = 1$. The network of Chua's circuits is described by Eqs. (1) with $m = 3$, $x_i = [x_{i1}, x_{i2}, x_{i3}]^T$, $H_0(x_i) = [x_{i1}, 0, 0]^T$, $H_0 = [1, 0, 0]^T$, and $F(x_i)$ given by
The parameters are chosen so that the Chua’s circuit is chaotic in the double scroll regime: $x_c = 9, \beta_c = 14.3, m_0 = 1/7$, and $m_1 = 2/7$.

The network of Rossler’s systems is described by Eqs. (1) with $m = 3, x_i = [x_i, x_{i2}, x_{i3}]^T, H(x_i) = [0, x_i, 0]^T$. To make the time scale similar to that of the other systems investigated.

The network of Chen’s systems is described by Eqs. (1) with $m = 3, x_i = [x_i, x_{i2}, x_{i3}]^T, H(x_i) = [0, x_i, 0]^T$ and $F(x_i)$ is the Master Stability Function (MSF).

The following parameters have been chosen: $a = 3.57, b = 0. 2, c = 28$. The Chen’s equations are scaled by a factor equal to 0.5 to render the time scale similar to that of the other systems investigated.

Eqs. (1) are integrated with the Euler-Maruyama method for a window of duration equal to 2000 with a time step of 0.001 (which is a time step adequate for all the three networks’ construction). If for all eigenmodes with $\gamma < 0$, then the synchronous state is stable. The stability of the synchronized network is calculated by evaluating the sign of $\delta = \text{det}(\mathbf{A}_c)$. The network synchronizes in the absence of the noise. This selection is informed as type II MSF systems; and systems having a connectivity distribution (the probability that a given node has a given degree).

The parameters are chosen so that the Rosler’s system is chaotic: $a_0 = 0.2, b_0 = 0.2, c_0 = 9$. The Rosler’s equations are scaled by a factor equal to 10 to make the time scale similar to that of the other systems investigated.

The Master Stability Function. In our analysis, the coercive coefficient $\kappa$ is chosen so that the network synchronizes in the absence of the noise. This selection is informed by the Master Stability Function (MSF)

According to this approach, a block diagonalized variational equation of the form

$$\dot{z}_k = [DF - \kappa G^T D]z_k$$

represents the dynamics of the system around the synchronization manifold. Here, $\gamma_k$ is the $k$-th eigenvalue of $\Omega$, $h = 1, \ldots, N$, and $DF$ and $DH$ are the Jacobian matrices of $F$ and $H$ computed at the synchronous state. Therefore, the blocks of the diagonalized variational equation differ from each other only for the term $\kappa G_k$. To investigate the synchronization properties with respect to different topologies, the variational equation is studied as a function of a generic eigenvalue $\gamma$ (for the sake of simplicity, we limit the discussion to the case of undirected networks, for which the Laplacian has real eigenvalues). This leads to the definition of the Master Stability Equation (MSE):

$$\kappa = [DF - zD]z_k.$$

The maximum (conditional) Lyapunov exponent $\lambda_{max}$ of the MSE is studied as a function of $\kappa$, thus obtaining the MSF, that is, $\Omega(\kappa)$. Then, the stability of the synchronization manifold in a given network is evaluated by computing the eigenvalues $\gamma_k (k = 2, \ldots, N)$ of the matrix $G$ and studying the sign of $\Omega$ at the points $\kappa = \gamma_k$. If for all eigenmodes with $\kappa = 2, \ldots, N$, $\Omega$ is negative, then the synchronous state is stable at the given coupling strength $\kappa$.

In the literature, systems with always positive $\Omega$ are referred to as type I MSF systems; systems having $\Omega$ negative for $\kappa$ larger than a given constant are referred to as type II MSF systems; and systems having $\Omega$ negative only in a compact interval, that is, $\Omega < 0$ in $[x_1, x_2]$, are referred to as type III MSF systems.

All the systems investigated in this report have type II MSF so that our analysis is not biased by the MSF type.
